SCIENCE

FRIDAY, JANUARY 6, 1911

CONTENTS

Geology and Economics: PROFESSOR JAMES F KEMP 1

City Sanitation: PROFESSOR CHARLES BASKERVILLE . . . 16

Scientific Notes and News 21

University and Educational News . . 24

Discussion and Correspondence —

Symbols in Zoological Nomenclature: PROFESSOR HENRY B WARD *Botanical Evidence of Coastal Subsidence* H H BARTLETT *Faculty or President* PROFESSOR GREGORY D WALCOTT. *The Matter of University Fellowships* PROFESSOR EDMUND B. WILSON 25

Scientific Books —

Botany for Colleges and Universities: PROFESSOR CHARLES E BESSEY *Chesneau's Theoretical Principles of the Methods of Analytical Chemistry* PROFESSOR M A ROSANOFF *Arnold's Attention and Interest*: PROFESSOR ROBERT MACDOUGALL 33

Special Articles.—

An Intermittent Spouting Well. PROFESSOR E H SELLARDS. *Graphite in Vein Quartz* OTTO VEATCH. *Concerning Sexual Coloration*: DR. J. GRINNELL . . . 37

The Oklahoma Academy of Science: D. W OHERN . . . 39

The Association of Teachers of Mathematics in the Middle States and Maryland: HOWARD F HART 40

MSS. intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

GEOLOGY AND ECONOMICS[1]

DURING the century which has just closed, the various branches of natural science, botany, zoology, geology and their relatives, having earlier completed their childhood, attained to the well-rounded development of maturity Their broad truths were given clear expression, they were widely apprehended, and they became the foundations of various inventions and applications of far-reaching influence upon human welfare Geology, although closely bound up with agriculture, has, nevertheless, been especially concerned with mining And justly so, because its contributions to the art of mining have been no more than a filial return, since mining as practised in the middle ages was the parent of geology Until recent years geology's services to the industry have been chiefly rendered in spreading sound and reasonable ideas regarding the nature and distribution of the useful minerals, in solving the perplexing structural questions affecting their occurrence, and in facilitating the discovery of new fields.

The problems of the production of the metals and non-metalliferous substances, as we know them to-day, are of quite recent growth. High explosives, efficient engines and pumps, steam shovels and the like are all not so old as many men who are still living. They have so greatly reduced costs that practically a new world has opened to the miner. Not only on the surface or near it has he been able to work, but the depths have become accessible, and where the value of the ore justified the ef-

[1] Presidential address before the New York Academy of Sciences, December 19, 1910.

fort, no floods of water have sufficed to keep him out

These successes coupled with ever-expanding markets have until recently directed attention almost wholly toward discovery and production But the last ten years have brought a further change We are now less concerned about new discoveries than about the maintenance of old ones We are not altogether intent on production, but are much given to forecasting and husbanding. From being solely an aid to the miner, the active worker, the producer, geology has become the colleague and helper of the economist, the statistician and the philosopher.

Like all other changes in fundamental points of view, this one has not come with absolute suddenness As far back as 1879 certain geologists and engineers began to raise and discuss the question of the duration of the Pennsylvania anthracite. In 1894 the late Richard P Rothwell, long the able editor of the *Engineering and Mining Journal*, gave these coal fields a future of 70–100 years Thus for over thirty years the question of their death has been a very live one Even earlier the future of the coal-fields of Great Britain came up for discussion A parliamentary commission was appointed in 1866 and reported upon the question in 1871. For forty years anxiety has prevailed regarding the continued production of our petroleum wells, and naturally so The very means of production of this useful source of heat and light starts a train of thought along the lines of its permanence.

Some ten years ago, the question of our reserves in iron ore began to excite interest. Mr. Andrew Carnegie gave most forcible expression to the feeling of alarm in his rectorial address in 1902, at the University of St. Andrews, Scotland. Mr. Carnegie was known from one end of the world to the other as one of our greatest iron-masters and his words made a profound impression In his address he assigned us only enough first-class ore to last for sixty or seventy years, and only enough of the inferior grades for thirty years thereafter. We all trembled for some years with the prospect of seeing our greatest industry in the production of metal, disappearing within a century Many thoughtful people began to wonder what would become of us with its extinction.

I have thought, therefore, that it might be not without interest if we take up this evening the more important of our metals and pass in review some of the fundamental facts of their production, the yield of their ores, the foreign sources, the future probabilities and the effect upon the civilization of our own and other lands which would result from their curtailment. In a word, we may for a time discuss geology and economics.

The iron industry in the United States took its rise in the colonies along the Atlantic seaboard—and at the outset was based upon the magnetic ores and brown hematites there occurring. For one hundred and fifty years its growth was slow. In the decade of the forties and fifties of the past century it had spread to the Adirondacks and in the fifties began its development in the Lake Superior region. Not until after the close of the civil war and the resumption of peaceful activities did this great industry manifest its possibilities. With improved facilities of navigation which placed Lake Superior in easy communication with the coal-producing states of Pennsylvania and Ohio, the iron-ore-producing states of Michigan, Wisconsin, and later Minnesota, came rapidly into prominence. In somewhat slower growth Alabama, during the seventies and eighties gathered headway. At present four fifths

of our ore supply comes from the three Lake Superior states, and three out of the four fifths from Minnesota alone. Alabama, Tennessee and Georgia together yield one tenth and the remaining tenth is divided among a dozen or more other states, of which New York is the leader. Since 1880 the total has increased about sevenfold and Pennsylvania, then the source of about one quarter the supply, now yields approximately one and one half per cent. Minnesota, now the great source of ore, only entered the lists in 1884, and only began to utilize its present great mines about ten years later.

Thus in the brief course of thirty years there have been very great rearrangements not only in geographical sources of supply, but still more in actual amount of output. In normal, prosperous years the annual production is somewhat more than fifty million tons of ore.

But there have also been other changes not less striking. In early days and in remote situations only the richest ores could be mined. Magnetites for example in the lump from the Adirondacks afforded over 60 per cent. metallic iron. Specular hematites from the Lake Superior districts necessarily yielded 65. For some years no one regarded them with respect if they contained less. Red hematites from Alabama afforded forty-five to fifty. The minor ores near the furnaces were often much lower—but they may be passed over for the moment in emphasizing the larger features. Magnetites in the Adirondacks are now concentrated before shipping and in instances two and one half to three tons are condensed to one of 65 per cent. tenure. The crude ore carries 33–35 per cent. During the early years of the present decade the general average yield of Lake Superior shipments fell off about one per cent. per year—so that now the soft ores, so called in contrast with the hard lump specular of earlier days, range somewhat above 50 per cent. Alabama ores, once 45 to 50, now are very uniform at 36 to 37. So far as the brown hematites are concerned, which in the form of lumps, crusts, pipes, etc., are distributed throughout ochres and clays, the percentage of available iron in the crude ore is lowest of all. We wash from eight to ten tons of crude in order to get one ton of concentrates of say 40–45 per cent. in iron, and under favorable circumstances may treat much lower raw materials. Soft magnetites in Pennsylvania, which on the richer outcrops gave 45 to 50 per cent., are now dug in very large amounts with a yield of 43. If we take the total production of ore in the United States and the total production of pig iron, we find the yield in the large way to be about 50 per cent.

In order to gain some idea of the comparative merits of these figures when set alongside the percentages in the ores produced in other lands, a few cases may be cited. Germany in 1907 produced 27,700,000 tons of ore, exported nearly four millions and imported eight and one half millions. Of the local production three quarters were obtained from Elsass, Lothringen and Luxemburg, whose percentage in iron ranges between 30 and 40 and is on the whole not very different from Alabama's present percentages of 36–37. Germany's imports, of course, range much above these figures, else the ore could not stand the freight charges from mines in such remote countries as Sweden, Spain and Algiers.

Great Britain produced in 1907, approximately, 15,000,000 tons, of which about three quarters were the so-called impure carbonates yielding 30–35 per cent. iron. One ninth of the total was red hematite at 50–55. The general average would be somewhat less than that of Alabama. Im-

portations of richer ores, especially from Spain, helped to raise the furnace yield.

France in 1908 produced 10,087,000 tons, of which 88 per cent was mined in French Lorraine of the same type as the main German supplies The ore ranged from 33 to 40 per cent—again not far from the Clinton ores of Alabama We are justified, therefore, in saying that the largest part of the output of the next three producing countries of the world is about the same as the lowest grade of lump ore, which can be profitably mined under present conditions in the United States. When, therefore, we come to estimate comparative reserves we must realize that in the Lake Superior region—our greatest producer—we pay no attention to-day to ores, which are, nevertheless, much richer than those of Great Britain and continental Europe

In the opening sentences I spoke of the anxiety which was felt a few years ago regarding the reserves upon which the industry would of necessity rely for its future I mentioned Mr Carnegie's remarks in 1902 at the University of St Andrews But he was not the only one who discussed this question and now in referring to one or two other forecasts, I think you will have in mind some of the fundamentals which establish a correct point of view

In 1905 Professor Tornebohm, the eminent and greatly esteemed former director of the Geological Survey of Sweden, assigned to us a reserve of only one billion and sixty millions of tons Obviously, at an annual production of over fifty millions this reserve would only last twenty years. The future thus looked still darker than when seen through Mr Carnegie's spectacles Much opposition arose at once, however, to Professor Tornebohm's data, because from them had been omitted the red hematites of Alabama, which can be very accurately estimated and which of themselves are thought by competent observers to have a half billion tons for the future. Additional modifications must also be introduced when we properly appreciate the downward tendency of workable percentages The lower the percentage of iron which we require in the product of our mines, the greater the amount of ore which at once becomes available This is peculiarly true of iron, because of its very wide, general distribution

In 1907 in anticipation of the International Geological Congress of 1910, which was to be held in Stockholm, the Swedish committee of arrangements began the preparation of a series of estimates of iron reserves in all the countries of the globe. Geologists familiar with local conditions were requested to prepare the figures each for his own country It fell to the speaker to start the collection of American estimates and much aid was afforded by several of the largest companies owning reserves Shortly thereafter, however, the interest in the conservation of natural resources sprang up and Dr. C W. Hayes, of the United States Geological Survey, was empowered to use all the resources of this great organization in assembling data on iron. In this way figures as reliable as can be expected are now available. We learn from them that we may consider three and one half billion tons of fifty per cent ore as assured in the Lake Superior region Of this great total three billions, one hundred millions are in the Mesabi range of Minnesota At thirty millions of tons per annum, the present output of Minnesota, we have a reserve for a century

On the other hand, if we drop to 40 per cent. or slightly below, still, however, remaining a few per cent above the Alabama grade, the drill holes show above depths no

greater than those already reached in some mines, two or three hundred billions of tons of siliceous hematites, giving amounts practically inexhaustible.

In the Alabama ore beds we feel assured of five to six hundred million tons of the grades now utilized and there may well be twice that number. The conservative estimate would afford enough to last at the present output of that state longer than a century. In addition there is much reason for thinking that there may be two or three times as much

Speaking for the country as a whole, we may say that there is an assured and demonstrated supply, at present rate of output and at present percentage of yield, for about a century There is, furthermore, a less accurately measured but still very probable addition, when we allow for lower grade but still practicable ores, which will be sufficient to last at present rate of production for fifteen hundred years to come

If, however, production increases, as indeed it may with a rapidly growing population, and if in this way heavier and heavier drafts are made upon even this great reserve, where shall we look for more? There may be some new discoveries within the United States, but at present it is impossible to speak definitely of them. We may ask if there are other supplies in neighboring lands To this question we may answer yes. Along the north shore of Cuba, toward its eastern end and near the sea, three areas of what formerly appeared to be a barren, ferruginous soil have been discovered and tested, so that we now know that there are two to three billions of tons of a very pure iron ore, which, when deprived of the large percentage of water which it contains—a cheap and simple process—will yield from 40–45 per cent. iron. This variety of ore already begins to enter our ports and the deposits will undoubtedly contribute in no unimportant way to the output of our furnaces.

The report of the International Geological Congress has shown further that in Newfoundland there are quite probably more than three billions of tons of red hematite, whose present yield averages 54 per cent. From Brazil, moreover, in the state of Minas Geraes, but pretty well back from the coast and not yet opened up by rail, as estimated by Dr O A Derby, there are from five to six billion tons of 50–70 per cent ore awaiting the drill and the steam shovel Ore from Brazil faces a long sea voyage, but the grade is rich and the iron masters of this and other countries are looking upon these deposits as well within the possibilities of the future Ocean freights are kept at very reasonable rates in later days and once on a steamship even so low-priced a commodity as iron ore, if of good percentages and cheaply mined, can be taken relatively great distances This is demonstrated by the shipment this year from the mines of Kiruna, 112 miles within the Polar Circle in Lapland, of 300,000 tons of ore, 113 miles to the Norwegian coast by rail, and over 4,000 miles to Philadelphia by sea, with no great prospect of a return cargo. These shipments also demonstrate that we are not without the range to which European ores may be shipped when exceptionally rich Some portion of the vast ore body of Kiruna, with its demonstrated 500 millions of tons of 65–69 per cent. ore will also reach American furnaces.

But even were our actual ores of present grade to become exhausted, iron as a metal would not fail. The basic rocks with their low percentages still remain. The traprock of the Palisades contains 7–8 per cent. of metallic iron, a value that is far above the general yield of our copper ores in the red metal.

Iron, therefore, will never fail. It will probably not change in its general relations to modern conditions for a very long time to come, so far as its ores are concerned. We may have greater anxiety about the supplies of coking coals than about the iron ore, but there are always such possibilities of improvements or changes in processes that no one can justly give way to unqualified forebodings.

Copper is the metal generally considered next in importance to iron. It is a very old one in the history of the race. The bronze age, you will recall, preceded the iron age. Prehistoric man in Europe solved the mixed metallurgy of copper and tin before he learned the smelting of iron. Prehistoric man in America found native copper on the shores of Lake Superior and passed it in trade a thousand miles from its home. As a cherished possession it constituted his ornaments while he lived and it was buried with him after he had died.

Among the moderns, copper is most extensively employed in brass, but as a conductor of electricity it finds year by year increasing applications in the purest condition in which the metallurgist can supply it. If at home or in your office you look around your chair or desk you will be surprised to find how universally employed it is.

Greatly stimulated by the development of electricity in later years the production of copper has advanced by leaps and bounds. At present the United States are the heaviest producers, with Spain following next, but only yielding one eighth as much. The United States furnish over half the total. In 1850 the United States yielded 728 tons, in 1900 over 303,000 and in 1908, 471,000. Meantime in 1850 the price of copper was about 30 cents per pound. Its lowest point in recent years was nine cents in 1894. Its highest, 25 cents, was attained in 1907. We may each of us imagine the variation in the profits of a mining enterprise as between 11 cents a pound and 15 cents, let alone 20 or 25 cents. Mining costs, smelting and freight charges, show no such variation, so that with rising prices profits greatly increase. Indeed, few of the metals have such extraordinary ups and downs as does copper.

In its ores the yield varies greatly. On Lake Superior, where the native metal is distributed through ancient lava flows in little pellets, leaves and sheets, it has been profitably mined and produced through periods of years, when it constituted but three quarters of one per cent. of the ore. The general run is, however, one per cent. and above. If we recall that in a ton of 2,000 pounds one per cent. is 20 pounds, and three quarters of one per cent. 15 pounds, and if copper is selling at, say, 13 cents, the mining manager must break down, hoist, concentrate with attendant losses, and smelt an ore worth less than two dollars for all the metallic contents which it contains. We can thus gain an idea of the close and economical work required and the ability demanded of a manager. As the price rises the profits greatly increase, and temporarily idle mines are brought within the widening remunerative zone, and are quickened into life. As the price falls, the mines dangerously near the line close down and production ceases. The lowest cost of production claimed is from the low grade and very large ore bodies of the west and is placed at or about eight to nine cents per pound laid down in New York.

In copper ores outside of the Lake Superior region, we usually find the metal in composition with sulphur. The ores as they come from the mine may be rich enough to go directly to the smelter, or they may require concentration before the

grade is sufficiently high. The ores which are directly smelted reach the minimum of copper in the Boundary district of British Columbia, but associated gold and silver raise the value per ton above four dollars. Copper ores yielding copper alone were smelted at Ducktown, Tenn., during long campaigns at a little less than 2.5 per cent. In earlier years and in many mining districts ores as high as 20 per cent. were found, rarely even higher, but they in time were exhausted and five per cent. would be quite rich for day in and day out averages.

These statements will serve to establish a point of view and likewise afford a standard of comparison. What is the outlook for the future of copper production?

We can not predict copper with the certainty of iron. It seldom appears in bedded deposits which can be measured. In the deep mines we can not always see ahead for more than a year or two. In some mines we know from exceptionally complete development, of twenty years' supply. But the great advance in copper mining has been the entrance of relatively low-grade ores into the productive field. The wall rocks of ten years ago have become the ores of to-day. Where we find in porphyries or schists copper sulphide disseminated in fine particles or as coatings along crevices, and in sufficient richness to yield two to two and one half per cent., throughout very large bodies, it can be mined very cheaply and concentrated in enormous quantities so as to return a safe margin. If the ore lies near the surface, steam shovels make excavation extremely low in cost. The huge pits and open cuts of this type of mine in the west are now among the great sights for the traveler. Mills whose insatiable crushers take as much as eight or ten thousand tons per day are no longer unknown. The drill blocks out the ore long before mining begins, and reserves can be estimated more closely than in the vein mines.

If a mine is called upon to furnish a mill with 2,000 tons per day and we allow 300 working days in the year, 600,000 tons must be supplied per annum. For a life of twenty years, a time practically demanded of such an enterprise to justify the great expense of installation, at least 12,000,000 tons must be shown by the drill before the enterprise can safely begin. If we expect to mine three times this amount per day we call for three times as much ore. These figures, large as they may seem, are not beyond the estimates of ore bodies as now blocked out in several places in the west, and even with these great demands, twenty years supply and even more in instances have been demonstrated.

Let us now imagine again a 2,000-ton daily output of say 2.25 per cent. ore, of which the mill saves two thirds, or 30 pounds of copper in the ton. The output in copper per day will be 60,000 pounds, or 30 tons and for the year 9,000 tons. Should three new companies start up with four or five times this output, 36,000 to 45,000 tons will be added to a yearly supply, which in 1909 was 552,668 tons. We see great need of a growing demand in order that these vast contributions may be absorbed. Yet I have made no unreasonable assumptions nor have I overstepped the practical certainties of the next few years.

How long will our copper hold out? Mines come and go, and for the immediate future there will certainly be no scarcity. Copper does not oxidize as readily as iron and is not lost. The world's stock steadily accumulates. But twenty years is not a long look ahead. Are there new countries which will be producers? Some of the old mines in Europe are now no longer great sources of the metal.

We do know of possibilities in Alaska that will add some contributions We know of new or recently opened ore bodies in Peru, Bolivia and Chile that promise well We hear of very large deposits in the southeastern corner of the Congo State, once worked by the ancients, now revived by the moderns and possessing large reserves of 15 per cent copper ore The Cape to Cairo railway will give them great impetus For the immediate future there is no lack, but if we look fifty years or a century ahead we can speak with less confidence In a general way we may say that probably new discoveries will, for a time at least, more than keep pace with demands But when we look fifty years into the future we are not so certain It behooves the producers to use no treatment of an ore except a careful and economical one If tailings and waste from our mills now contain one third the copper in the original ore, they should be impounded and kept from being washed away by floods, against the possible call of the future We dare not say that they will never be within the ranges of profitable treatment even though their low percentage places the copper beyond reach to-day The copper situation is not one to excite anxiety, yet it is also one not to encourage extravagance

Following copper we may take up lead and zinc, which are the next metals in amount of production Of the three, zinc is the least in total tons and in total value We may gain some idea of the relations from the small table given below in which zinc is taken as unity and the figures relate to 1908

	Amount	Value	Price per Pound
Zinc	. 1 0	1 0	1 0
Lead	1 6	1 45	0 9
Copper	2 46	7 0	2 8

Thus we see that the lead production is one and three fifths that of zinc, and the copper is two and one half times, that the lead is about one and one half times the value of the zinc, and the copper is seven times, and that zinc is worth more per pound than lead and only about one third as much as copper. The red metal is not only produced in greater amount, but is worth more per pound and in the aggregate than both the others taken together.

Among the nations of the world the United States has become the chief contributor of lead and yields year by year proportions varying from 27 to 33 per cent. of the total The next country is Spain with about two thirds as much, and Germany follows with three fifths

In this country the state of Missouri is the heaviest contributor and is responsible for practically 40 per cent of the total. Idaho is next with about 32 per cent and Utah follows with 13 to 14 The western lead all carries silver The precious metal is an important factor in the value of the product When we come to forecast the future it is not possible to see more than a few years in advance or to speak in more than a general way The miners would be glad to be assured of reserves of ore for a goodly period of years, but it is seldom possible or practicable to demonstrate their presence Operations necessarily continue with a few years' supply blocked out in advance of the actual mining and the hope is maintained that more will be found. Very often the expectations prove justified. We may therefore in a measure forecast future experience somewhat by the past In the Missouri lead region mines have been operated for forty or fifty years, not on so large a scale at the outset as now, but continuously For some years at least no change may be anticipated In Idaho the lead ores are now known to continue to

depths of nearly 2,000 feet beneath the overlying surface and to be holding out without essential change in character. In Missouri, however, the mines never have been very deep, that is over three or four hundred feet, and the compensation comes in wide horizontal extent

Some of the old time heavy producers have greatly declined Nevada, once an extremely important source of lead, is now a comparatively small contributor Colorado, in former years our chief source, has dropped to only a third of its one-time yield, and yet the total of the country has gone quite steadily on The fall in the price of silver was a hard blow to the western lead miners and naturally not only cut off their profits, but raised the necessary percentage of metal in the ore

If we look ahead for a century or some such long period, we may not feel assured that production can be maintained at present rates There may, of course, be new discoveries in lands not as yet fully explored Being distant from present centers of consumption as they necessarily would be, their entry into the markets would imply higher prices so as to meet the charges of freight

On the other hand, lead is a metal which oxidizes or changes very slowly In its applications in the metallic state it tends thus to accumulate unless lost in use, as in the case of shot and bullets It is extensively employed in the manufacture of paint and in this form is of course never recovered About two per cent of the entire output is destroyed to give us white and red pigments

It behooves us on the whole to be careful in the use of lead and to avoid, when possible, its unnecessary sacrifice

Zinc is a metal of comparatively late introduction into commerce in the large way. Although known for centuries, it has found its chief applications in the last sixty years There was no zinc mine in the United States until approximately the year 1850, and from the Missouri region whence we now obtain our chief supplies, the really serious contributions began about 1870 Lead, indeed, was mined and prized long before this, but the associated zinc ore was thrown one side on the dumps In the west the same experience continued until much later Zinc was a nuisance in the metallurgical treatment of lead and even the lead was sought and smelted either because of its own silver contents or because it made possible the treatment of other refractory silver ores In the metallurgical work the zinc was volatilized or slagged off and was lost Indeed, one of our most serious metallurgical problems has been the successful treatment of lead-zinc ores and many investigators have addressed themselves to its solution Now that anxiety is beginning to manifest itself regarding zinc supplies for the future, the desire to save it is stronger than ever.

Zinc, however, is a peculiar metal and because of the exigencies of its treatment its ores must possess greater richness and greater purity than those of other base metals Thus in the case of copper a ten per cent ore is in later days phenomenally rich, and as it can be smelted in a shaft furnace the presence of iron or lime or other bases that make fusible slags is an advantage But zinc ores, perhaps after preliminary roasting, must be reduced and the metal must be volatilized at a high temperature from a small charge in a retort The presence of fusible bases destroys the retort and the bases are therefore debarred beyond certain small percentages Thus it happens that a forty or fifty per cent. zinc ore might be valueless if contaminated by iron or lime beyond a narrow margin While almost any con-

ceivable mineralogical aggregate that contained ten per cent of copper would be a very valuable ore, a zinc-bearing aggregate with four or five times as much zinc might be unsalable

Suppose we compare them from another standpoint Copper ores, if at all profitable, are worth about so much per unit of copper, that is, so much for each per cent While there is some variation yet the contrasts as among three per cent, five per cent and ten per cent ores are much the same as the ratio of the per cents to each other But if we think of a zincblende ore or concentrate of 60 per cent as the standard of richness, a fifty per cent ore is not worth five sixths as much, nor a forty per cent ore two thirds On the contrary a forty per cent ore might be entirely unsalable. As the zinc decreases other deleterious bases take its place and a worthless mixture soon results Zinc is in many ways the most peculiar of the metals and when we come to deal with its profitable treatment analogies with other metals fail

In 1907 the United States were the chief producer of zinc among the nations, but, as a rule, Germany leads, followed by this country and Belgium in the order named In later years our output has varied from 26 to 30 per cent of the total As a rule Germany is 2–4 per cent in excess of us and Belgium is 4–5 per cent less

In America, Missouri is the chief source of zinc Its production from the mines was in 1908, approximately one half the output of the entire United States New Jersey follows with somewhat over one quarter the total, while all the rest are much smaller

The Missouri ores as thus far produced have been obtained from comparatively shallow depths They extend lengthwise and sometimes laterally to greater dimensions than vertically While it is not beyond the possibilities that lower lying deposits may be discovered, since zinc ores are found in Arkansas in strata of lower geological position, anticipations of this reserve have not as yet been demonstrated on a large scale Kansas, Oklahoma and Arkansas, the states neighboring to southwest Missouri, also have some zinc ores, but they are not of great importance, southwestern Wisconsin is a very old mining district and has many small mines, which were earlier worked for lead. They have been revived for zinc in later years and are now an appreciable but not great factor They may develop somewhat more extensively and may last for a goodly series of years, but the mines are relatively small and are wet, so that exploration does not go very far in advance of mining.

In New Jersey the future is best forecast of all For thirty or forty years there is no occasion of anxiety Yet thirty or forty years pass quickly and then we must prepare to look for other sources To make the zinc blende of the Rocky Mountain region available, an increase in price is practically necessary, otherwise the metal can not stand the freight charges There is zinc ore in the west but to what extent we can not well say It has been avoided rather than sought in most of our mines. Yet we do note symptoms of attention to it In Butte, Montana, efforts are being made to concentrate it Shipments of oxidised ores have been made from New Mexico for some years past Until recently large amounts of peculiar appearance seem to have been overlooked at Leadville, Colorado. They promise to be an important resource. A government commission has reported upon the occurrence of the metal in British Columbia in the hopes of utilising the ores. From Mexico, too, we learn of explorations for zinc. Conditions are changing in the case of this metal and

more and more it is certain to be brought from remoter localities But when we look a long way ahead, say for a century, we can not feel free from anxiety. This condition of mind is even more prominent in Europe than in America. The waning of the famous old mines near Aix la Chappelle, and the apprehensions felt regarding other sources, have led to a world-wide search. Zinc ores, for example, now reach Hamburg from the Pacific shore of Siberia, and as other discoveries are made, additional points remote from present smelting centers are likely to be shippers, provided that transportation is by water Nevertheless, all these new conditions call for advances in price and before many years zinc bids fair to take the upward course

The precious metals, silver and gold, are the only other two which we may pass in quick review Silver is a less profitable object of mining than it was twenty years ago, and yet with the improvement of processes of extraction and with the great development of the output of copper and lead in which it is a by-product, the fall in its price of the early nineties has been less disastrous to the amount produced than one might have supposed. Our maximum output was reached in 1892 when it was 63,500,000 ounces valued at $55,662,500 In the same year about 1,600,000 ounces of gold were produced valued at somewhat over thirty-three millions of dollars. In 1908 we are credited with approximately fifty-two and a half million ounces of silver, valued at twenty-eight million dollars. Gold, meantime, with the fall of silver, has advanced to 4,574,340 ounces, valued at $94,560,000.

In the United States we have now comparatively few distinctively silver mines. Among them Tonapah, Nev., has been chief. Mexico is the particular home of silver, but the remarkable district of Cobalt, Ontario, has given great present importance to Canada. In our own country we must expect the white metal to share the fortunes of the copper and lead with which it is chiefly produced As influencing its future, copper is a more serious factor than lead, both for the reason that Missouri lead contains little if any silver, and because western copper ores display greater reserves than do western lead ores. As sources of silver there were in 1908 no very great differences among Montana (a copper-silver state), Colorado (a silver and lead-silver state), and Nevada (a silver state). Utah (both a lead-silver and a copper-silver state) afforded about five sixths Montana's output, and Idaho (a lead-silver state) about three fourths Montana's,[8] Arizona (a copper-silver state) follows after a long interval, and the others are much smaller

As an indication of relative magnitudes, while the output of the United States was placed at 52 5 million ounces in 1908, Mexico afforded 72 6 and Canada 22 millions Australia with 17 3 follows and then Peru with 7 2 millions. A metal with so high a value as silver will stand transportation from remote points, and although the production in one country or another may fluctuate, the world's supplies are not likely to be seriously affected for many years. Silver is largely used in the metallic state, and, being resistant to change, it tends to accumulate. Photography is the most destructive industry to it, and when once employed in this art, it is practically lost

[8] In ounces they range

Montana	10,356,200
Colorado	10,150,200
Nevada	9,508,500
Utah	8,451,309
Idaho	7,558,300
Arizona	2,900,000

Gold is mined for itself alone to a far greater degree than is silver. Thus in this country in 1908, almost 93 per cent. of the gold was produced without regard to other metals and only 7 per cent. was obtained with copper and lead, whereas about 60 per cent. of the silver was produced in association with the base metals. Gold in later years has increased in amount of production beyond all previous experience. The steady and scientific digging and washing of low-grade gravels are, in the long run, more productive than the rich skimmings of the early California, Australia and Klondike placers. The world's total of 444 millions of dollars in 1908 was in excess of any previous year. The Transvaal furnished the most, nearly 146 millions. The United States followed with 96 millions, Australasia yielded 72.5, Russia nearly 40, Mexico, 24.5, Rhodesia, 12.2 and British India, 10.4. All the rest were under 10. The countries mentioned supply about 90 per cent. of the total.

In the United States 28 per cent. of the gold comes from gravels and these are the least permanent of the sources of the metal. With their exhaustion the output will decline. In the deep mines there are signs of waning output in some districts. In our own country new districts have come to the front from time to time to give on the whole a steady increase in output for forty years past. So far as the future is concerned, however, the ups and downs of any one or of several countries make slight difference in the world at large. Gold can be readily shipped from point to point and the place of its production is a comparatively small matter.

Like silver and to an even greater degree it resists chemical change, so that the world's stock constantly augments. No very important portion is permanently lost in the arts.

Gold and silver are so extensively employed in coinage that they have received more attention at the hands of economists than have any other metals. Gold in later years, with its increasing production has led to much philosophical speculation. The establishment of it as the monetary standard and the elimination of silver from this position have occasioned some of the most heated political controversies in the history of our country. Into these a geologist is not competent to enter. We all probably realize from old-time experience how easy it is to become befogged. But the geologist can say that for some years to come the gold production will undoubtedly be maintained. And that while the Klondike and Alaska may wane, Siberia will increase.

We may now briefly summarize the main facts affecting the six metals which have been passed in review. It will then be possible to draw some general conclusions. Of iron ore there is no lack, nor need any one be apprehensive regarding the supply of this metal, but before very many years have passed the yield of the ore will have decidedly declined. While the falling off will be gradual, it will undoubtedly tend in the long run toward forty per cent. This change is in itself important because, unless otherwise neutralized it will raise the cost of production. It makes necessary the melting of more barren materials in the furnace, so that the consumption of fuel rises with respect to the amount of iron produced. It means also the mining and freighting of an additional burden which yields no return. From whatever point of view we regard it, other things being equal, the cost of production rises. The great reserves of lower grade ore than at present mined are in the Lake Superior district. They are siliceous ores, and will require in smelting the admixture either of limestone

or of other iron ores high in the bases. The Clinton ores of Alabama are of this type and except for the unfortunate percentages of phosphorus which they might add to Lake Superior ores, they would doubtless make an advantageous mixture with the latter. But the southern ores are remote from the northern. In order to meet them at or near the supplies of fuel a long railway haul would be necessary. While this is not impossible, it would add to the cost so greatly as to be highly improbable. There is one further consideration. The greater part of our pig iron is used in the manufacture of steel. For this purpose in the two processes most extensively employed hitherto, we need, respectively, either a very low or a fairly high percentage of phosphorus. If our irons are in between, and like the church at Laodicea, neither hot nor cold, they have been ill-adapted to steel manufacture. Unless the growth of the open-hearth process introduces great changes, the mixture, therefore, of southern basic ores and northern siliceous ones is not altogether promising for this reason.

The greatest cause of apprehension as regards present processes of iron manufacture lies in the supply of coking coal. We have built lofty furnaces, and in their use we place upon the fuel as it progresses downward in the furnace a heavy load of overlying ore and limestone. We need a very strong coke to stand up under the burden. The coals which yield these high-grade cokes are found in a small portion of the total coal-bearing area, and the life of the supply is one of the very serious phases of the present situation. I do not know what the amount of reserves may be.

While these physical and chemical factors operate to increase costs, there is always the possibility of improved processes and of greater efficiency to keep them down. The improvement oftenest in people's minds to-day is the utilization of water powers to generate electricity, which in turn may supply heat. Now, in a blast furnace smelting iron ores, one third the fuel is employed in reducing the iron oxide and two thirds in developing the necessary heat for the reaction. Were we able with water powers to economically furnish electricity and from it derive the necessary heat we might save the two thirds of the present amount of required fuel. We might reduce costs. The remaining one third of the fuel we should always need but it is possible that poorer grades than high quality coke might answer. The saving would lie, of course, in the difference between the cost of the fuel and the cost of the electric current, provided the latter could be furnished more cheaply than the former.

The water powers in our own country or at least in the more thickly settled portions of it, have not failed to attract attention, nor have they gone altogether unutilized. The more conveniently situated ones are already harnessed to the dynamos. But in countries like Norway and Sweden, where there are large water powers still available, where there are rich deposits of ore and where coal fails, the applications of electricity to iron smelting are likely to be first worked out successfully. Data may be furnished in the life-time of many of us, which will cast light upon these improvements in their world-wide relations.

The only other apparent possibility of reducing costs lies in the labor charges. Wages at present are not unduly high, and unless the increasing population of the country brings to pass an inevitable struggle for existence, which will cause the greater subdivision of tasks at lower proportionate returns or unless the general reduction of expenses for subsistence makes lower wages possible, there would seem to

be slight prospect of change in this item. In any event the reductions from this cause can not compensate the falling off in the yield of iron as foretold above.

Suppose iron goes up in cost—other conditions of our daily life remaining the same—transportation and all manufacturing based on machinery would become more expensive, and less freely carried on Undoubtedly an appreciable pressure would be developed to turn our people back to the rural districts and to tilling the soil for a livelihood. The tendency under the stimulus of manufacturing development has been the other way. The migration of late years has been toward, not from the cities Shall we perhaps find in the long run, in the increasing cost of iron and steel a partial solution of a much vexed problem? Will the cry "back to the soil" receive support in a way not generally anticipated? The question is an interesting one for speculation.

The general inference regarding copper is that the pinch of higher cost of production will be felt sooner than in the case of iron. We have no knowledge of such enduring reserves of copper ores as we have of iron On the other hand, copper, despite its vast importance, is not the fundamental necessity that is iron. It is used in less quantity in machinery and its increase in cost would less vitally affect manufacturing industries based on machinery. Advancing cost would cut it out of much ornamental work of inferior esthetic merit. The most serious effect would be found in raising the expenses of service in the applications of electricity. Electrical transportation, telegraphy and telephony would be more expensive than to-day. Unless wireless methods of transmission eliminate copper, or unless some discovery in the domain of physics which we do not now foresee furnishes a substitute for the omnipresent copper wire of to-day, we may find ourselves face to face with some curtailment in these modern aids to the easy conduct of life's affairs If in the course of several centuries the falling off in supply and the growth in population should raise copper to relatively high figures, we may wonder if a return in a way to the conditions of the middle ages will not result. Will copper then become to a greater degree than now the basis of skilled handiwork? Will the by-gone craftsmanship be revived and with a lessening total output shall we see an advance in artistic skill? In fact, if the vast development of machinery and the huge output of metallic objects at low cost—a condition so characteristic of to-day—should be checked or curtailed, would not hand-work on more valuable mediums of expression be restored It is not altogether unreasonable to anticipate fewer objects and higher crafts in their production.

The cases of lead and zinc are even more emphatic than that of copper. We have still fewer assured reserves and the pinch of increasing cost may manifest itself at an earlier date The two metals are not, however, quite such vital factors in modern life as is copper and the larger effects would be less apparent. Zinc is a necessary component in the manufacture of brass, which industry absorbs the greater part of the copper output A curtailment of either lead or zinc would cause inconvenience, but would scarcely occasion fundamental changes.

Silver will be very seriously affected by a decrease in the output of either copper or lead. Gold will feel these changes in an appreciable but far less degree. There will always be sufficient, however, of each of the precious metals for coinage, and beyond this use their applications, except perhaps in photography, concern luxuries rather

than fundamental necessities We can not attribute to them any profound possibilities in their influence upon civilization should the contributions of the mines decline In the recent past we have been more apprehensive regarding a too great supply of the precious metals, than regarding one too small

With the increasing interest in the discussions of the conservation of natural resources, there has been an increasing disposition of the authorities to assume supervisory powers over mining and metallurgical operations The old-time idea that to the crown, or, as we are accustomed to say, to the state, belongs the mineral wealth of the earth, is experiencing something of a revival The disposition to restrict the waste of valuable metals or minerals in processes of manufacture is commendable and after careful demonstration that it is feasible and just to the operating concerns, it may be wisely done The rejected product of concentrating mills or the "tailings" so called, when provided with appreciable percentages of metals, may well be stored where they can be utilized by future generations, if processes improve so as to make them available. That is to say, they should not be run into rivers, or placed where they will be dissipated. The same remark applies to slags from metallurgical works. The moderns, for example, are now working over the lead-bearing slags left by the ancients at the great lead mines of Laurium, Greece. Even the slags of early smelters in the west and Mexico may again pass through the furnace.

Another question relates to the discovery, location and ownership of mining property. So far as the metals are involved, and with the metals this address has been alone concerned, the valuable discoveries are so few in comparison with the disappointing attempts to develop, that only by encouragement and rather generous conditions will the prospector be enabled to follow his arduous calling. He must be offered large prizes proportionate to the many failures He must be assured of possession by a very circumspect and conscientious administration, if confidence in the justice of the government is to be maintained People in the parts of the country where mining for the metals is not carried on hear only of the great successes and little of the innumerable disappointments Far the largest part of the population thus acquire very distorted views of the real conditions of mining The interference by the government other than in the ways which I have mentioned and in maintaining reasonably safe conditions for the workman, is a matter to be regarded with great caution, lest irreparable injury be done to the large problem of maintaining our future supplies with such new discoveries and developments as may be feasible The wisest course is to improve the method of establishing and recording titles to new discoveries, and then, except in the matters already mentioned, to let the natural course of business assert itself The proper share of the state will be obtained through the normal processes of taxation.

The mines for the metals do not, however, present the most important phase of this subject Coal is a more serious problem, and one demanding more extended treatment than would be justifiable in an address primarily devoted to other themes. One may only express the hope that where cases of dispute arise they may be determined in the courts, according to the established rules of evidence.

The resources in the metals which have been found in the United States have proved so great as to make the industries based upon them a very vital factor in our

whole civilization Great changes in the supply or the cost will inevitably react in the long run upon the opportunities for employment and support, and upon the very nature of our national life While it will be a long time before rearrangements in the case of the most important of the metals, iron, will be manifest, and while they will assert themselves gradually, we are quite certain to face new conditions in copper, lead and zinc at an earlier date In the end, however, we can perhaps justifiably forecast a future in which agriculture will figure more and more prominently and in which the moral, intellectual and spiritual life of the nation will readjust itself accordingly Great and concentrated wealth is likely to be less in evidence, materialistic influences less pronounced, and from the vantage ground afforded by the greater comforts and opportunities of modern life as compared with that of a century or a half century past, we may in the distant future look forward to an evolution upon somewhat different lines Broadly viewed, the national life will probably be increasingly sympathetic with art and with ideals

CITY SANITATION[1]

Great cities have grown and passed out of existence The enormous increase in urban population in very recent years has produced even greater cities, which may also in time cease to be In fact, aside from the possibility of local or cosmic calamity, this is sure to occur, unless due attention is given to the application of the principles of chemistry in our daily, personal and communal life London, Paris, Bombay, Rome and New Orleans have had their scourges in the past to testify to the fearful penalty of ignorance and neglect

Indications point to an urban growth and development, the conception of which taxes the imagination When we see New York as it was two hundred years ago, and then one hundred years ago, and as it is now, we may well wonder what it may be fifty years from now The annual increase in population is about 300,000. It has been calculated that in 1920 New York may have 7,000,000 of people

It has been predicted by a close and conservative student of sociology that two generations may see the eastern part of our country mainly composed of contiguous cities In 1790, 3 3 per cent of the population of the United States was urban It was 33 1 per cent in 1900 The problems of the state and county become closely interwoven with those of the city The city will no longer be merely an accumulation of human beings in a particular locality, with its local problems and influencing the state mainly in a financial way, but the city will have become the state

The individual needs fresh air, pure water, good food, safe shelter, and should have a clean body and something beautiful to look at When he associates himself into a city his needs are not lessened, but emphasized The growth of a city causes it to assume, willingly or no, corresponding obligations The inhabitants must breathe, they must be fed and watered, its wastes must be got rid of, facilities for the safe coming and going of its people at all times must be provided, as well as protection from fire or other adventitious circumstances which concern the welfare of the citizens The needs thus simply stated are to be met by obligations which become more and more complex with the increase in population In fact, most of the city's problems are of comparatively recent date

[1] An address at the tenth Conference of the Health Officers of the State of New York, Buffalo, N. Y, November 17, 1910

With your permission I shall address my remarks to certain specific matters which have come under my observation in Greater New York, and to which I have given special study. No doubt these matters have already been considered in some of your conferences, but the public expression of the independent point of view of one unhampered by official ties may serve one good purpose, namely, of provoking discussion, which can be made profitable.

The consideration of the air of cities involves not only the principles of ventilation, which will not be considered here, but the construction of the streets, means of transportation, the disposition of wastes, and the handling of the more unusual contaminants, which vary with conditions.

There are more than 2,000,000 miles of public roads in the United States outside of municipalities. These roads in many cases are essentially the same as we find in the outskirts of our larger cities, and are the roads of the smaller towns. The town roads are traveled very much more, so the actual facts at hand for the average road are applicable to the town roads, for which no satisfactory data are available. Cushman has calculated that 500,000 tons of dust are raised on the public roads per day, or, taking 100 dry days in the year, 50,000,000 tons of material are taken from places where it is needed and placed where it is undesirable by the movement of ordinary vehicles. A discussion of economic principles of road conservation is not germane to our subject. Suffice it to say that the modern motor-driven vehicle is not a dust maker, but a dust raiser.

The dust problem did not begin with the introduction of the automobile, although it has undoubtedly been accentuated by this mode of travel. There are sections of our country at the present time where the roads have been rendered practically dustless, and neither horse drawn vehicles nor automobiles can now deposit the dirt of the highways in the gardens and houses of abutting property owners. This condition of affairs did not exist before the introduction of the automobile, but has been arrived at in answer to the demand which has followed its use. In short, there are many suburban communities in which life to-day is far more agreeable, pleasurable and possible than it was before automobiles came into use.

Why may we not have this in every city?

Aside from the personal discomfort from flying particles of solid material, whatever be its nature, these particles are the bacterial aeroplanes. Sedgwick has shown that 10 liters of air taken five feet above a macadamized street in a dust storm may contain as many as 200,000 micro-organisms.

There is a natural fouling of the street surface and an unnatural fouling. The natural comes from excrement from animals,[2] detritus from wear of pavements, soot and dust from the air, leaves from the shade trees, and the grindings from tires and shoes. The unnatural, or, rather, avoidable causes are refuse thrown or swept upon the streets from buildings, refuse thrown by careless users and refuse spilled from vehicles carrying material through the streets. The latter causes are supposed to be prevented by the operation of ordinances which are honored in the breach, and these causes result in the greater cost of cleaning,[3] as the sweeper has considerable work in collecting litter before attacking the dirt, and the material is bulky.[4]

Commissioner Edwards, of New York City, says in *Municipal Chemistry* that

[2] One thousand horses will, in every working day of eight hours, deposit about 500 gallons of urine and 10 tons of dung upon the pavements. "On the Utilization of Stable Waste," see Birchmore, *Journal of the Society of Chemical Industry*, 1900, Vol. 19, p. 118.

[3] For cleaning all the boroughs in Greater New York of garbage, ashes, refuse and street sweepings, the Board of Estimate and Apportionment allowed an appropriation of $7,418,299.20 for 1909, and this amount was divided among the boroughs, Manhattan receiving $4,230,441.70, The Bronx, $560,371.30, Brooklyn, $2,492,481.20, and for general administration, $135,005.

[4] Very, "Municipal Chemistry," McGraw Hill Pub. Co., 1910, p. 243.

There are two general methods for disposing of street dirt, namely, it may be picked up, swept up, or shoveled up, and then hauled away, or it may be washed into sewers through the agency of water, or there may be a combination of these methods[5] As a rule, a considerable portion of the dirt is conducted away during rain storms, and some cities have especially constructed their sewers with the view of conducting off all dirt which can be reasonably emptied into them, in fact, it may be said that many municipal engineers consider that the sewerage system of a city should be constructed in such a way that it will carry off a large portion of the fine dirt from the streets

I will go further and say that the streets should either be made dustless or wet down with dilute chlorine water, that is, a solution of bleaching powder, or other disinfecting fluid Both methods have been used with success and are within reasonable cost

The topography of a district in which urban population has massed itself will, in a measure, regulate the mode of growth Although improved methods of rapid transportation have overcome the necessity of concentration, yet business and other causes continue to make for centralization, with consequent elevation in the value of land, whose acreage is increased only by vertical expansion The modern subway comes as a result. The air from the streets is sucked into these human mole holes It is to be hoped that the Public Service Commission will not allow the construction of any more subways, or that subways be built in other cities, except that the tracks be separated by partitions, or that the tracks of trains going in opposite directions will be kept in different compartments These have now been included in the specifications for the proposed subways in Greater New York For, although much street air enters the tunnels in New York at present, a large portion of the air is simply churned by the passing trains and not quickly and properly replaced. The ventilation in the London Tubes and in the Pennsylvania-Long Island Tunnels is excellent

There are many incidental impurities in city air that are local and more or less evanescent. I have shown that in the city of New York about 1,300 tons of sulphur dioxide are poured into the air daily in the combustion of coal. This is a sad annual economic waste of a most important chemical, some millions of dollars in value, which we do not know how to avoid or save at present

The smoke problem has confronted every city where coal is used as the main fuel. Civilized nations are only beginning to awaken their "conscience of fuel." Our methods of utilizing coal give us a return of only five per cent. of its energy when burned, and only one per cent when we convert that energy into electric light in the city.

Good firing is admittedly an important factor in smoke prevention, and it has even been regarded as the main factor of the problem,[6] but many authorities favor the distribution of gas as a means of at least alleviating the smoke nuisance.[7]

There have been many complaints against some of the railroads running out of New York City, because of the nuisance caused by their use of soft coal. Some of the suburban towns have taken legal action to prevent this. The solution of the smoke problem on the railroads reduces itself to the use of hard coal or oil, as the application of mechanical stokers and smoke-consuming devices to locomotive engines has

[5] Vacuum street cleaners have so far proved to be too expensive

[6] Caborne, *Jour. Roy San Inst.*, 27, p 142.

[7] For example, Lodge, Des Voeux, A. J. Martin and A. S E. Ackerman; in this connection, see *Jour Roy. San. Inst*, 27, pp 42, 64, 80, 85.

not proved to be a success, or better still in electrification.

The theory of Rayleigh[8] for dispelling fog, and with it smoke, by electrification is interesting and is demonstrable in a beautiful way on a laboratory scale, but the expense entailed and practical difficulties involved preclude its favorable consideration. However, this method is being used with more or less success in some of the smelters in the Pacific states.

One of the worst smoke nuisances about New York during the past few years has been caused by the garbage and other reduction plants at Barren Island[9] During this process of reduction, oil and grease are extracted from animal and vegetable matter, leaving a dry residue, which is used as a base for the manufacture of commercial fertilizers, the discarded residue being burned in the plant as fuel.

At another plant in this same point the carcasses of the larger dead animals, which are transported by a regular line of boats, are burned When the immense number of carcasses ordered removed annually by the New York Department of Health is taken into account, it is not surprising that the smoke given off with the accompanying odors should give offense to residents for miles around The number removed during the past year included 19,000 horses and about 380,000 dogs and cats, besides about 1,000,000 pounds of condemned meat, about 80,000 pounds of "too gamey" poultry, about 3,500,000 pounds of fish and about 5,000,000 pounds of offal.[10]

The necessity for a suitable supply of potable drinking water is now well recognized in every civilized community, and it is usually provided in the city, often at great expense, yet an appalling degree of ignorance is still encountered in the country districts that is difficult to overcome A large percentage of urban population does, and it is most desirable that every single individual in the city should, enjoy a few days or weeks in the country in the summer The ignorance of country habits is proverbial with the urban citizen, who takes certain matters for granted It is, therefore, not infrequent that these outings, picnics, etc., which should make for the better health, are the direct causes of unnecessary illnesses attributable directly to the drinking water, for all the liquid refreshments on these occasions are not limited to the national German beverage.

This is largely a matter of education Every teacher of chemistry has a splendid opportunity to drive these simple matters home, and I never fail to do it with the five or six hundred young men who sit under me every year But every citizen does not listen to lectures on sanitation, although frequent opportunities are given by the various lecture bureaus Popular bulletins, such as those splendid sheets which come so regularly from Dr Evans's office in Chicago, can do much good The press, when appealed to, will render great assistance

The public is inclined to believe that when an ample potable water-supply has been provided, all that is necessary has been done Sanitarians know that the contrary is the case. They may point out to the citizens that sewage disposal is quite as important. They may cite the story of Dantzic, which had good water in 1869, but the typhoid rate did not decrease materially until 1872, when sewers were added Vienna had good sewerage and bad water up to 1874; the death rate was 340 in 100,000 That year good water was supplied and the rate dropped to 11 in 100,000 With good water and no sewage the soil becomes saturated with refuse matter, a hot bed awaiting the planting of pathogenic bacterial seed Sedgwick, referring to cholera, figuratively states that "Pettenkoffer has given the key to the whole situation by saying that filth is like gunpowder,

[8] *Jour Roy. San Inst.*, 29, p 42; and *Elec Rev*, 47, p. 811

[9] Parsons, "Municipal Chemistry," McGraw-Hill Publishing Co., 1910, p. 333

[10] Parsons, *loc. cit.*

for which cholera is the spark. A community had better remove the gunpowder than try to beat off the spark, for in spite of their efforts, however frantic, this may at any time reach the powder, and if it does, is sure to blow them to pieces." The next great problem that New York City must solve will be that of sewage disposal. It will involve an expense vastly greater than the colossal sum now being spent for the magnificent new water supply.

Half the cost of living goes to pay for food. The centralization of population requires its transportation to the centers, but it does not enforce its exposure, uncovered in the streets or shops, where it collects the dirt and attracts flies. For a century it has been known that certain kinds of food could be preserved for later consumption without injury to health. There is no objection now to the preservation of food, provided it is done in the proper, that is, harmless manner. The adulteration and sophistication of food are outgrowths of the development of the city and the improved means for world-wide transportation, coupled with the degeneracy of those who live by bartering and their desire for luxuries. The chemist has been the Cartouche and Sherlock Holmes in the abominable business. Yet ignorance and disregard for the consequences so long as gain resulted have been behind the supply of one particular food, milk, which is the main support of the weak and helpless. The government has formulated satisfactory laws against the adulteration of the coin of the realm and enforces them vigorously. We have food laws now, but they are not satisfactory, nor are they always properly enforced. In fact, they can not be fully enforced as long as they admit of constant quibbling as to the meaning of common words in our language. No doubt these objections will be removed, for it is a time of fuller awakening to the conscience of our civic value.

Clothing which has been exposed to such infectious diseases as diphtheria and smallpox, is now destroyed or duly disinfected, at least theoretically. This is not the case with clothing, either second-hand or new clothing, made in the sweatshops, where we know tuberculosis is rampant. Clothing thus serves as a means for the spread of infectious diseases. This can be stopped by requiring new clothing to be thoroughly disinfected before allowing it on the market, or, better, by applying the old Mosaic law enjoining the strictest cleanliness. Moses really anticipated our modern sanitary laws, for cleanliness is the beginning and the end. The existence of sweatshops is one very dark blot upon the page of our vaunted civilization.

The problems of city sanitation no doubt can all be solved with unlimited means and unrestricted legal power and the machinery for exercising it. Practically, however, the economics involved affect the situation. Successful manufacturing enterprises usually begin with experimental plants and furthermore keep them constantly in operation afterwards as an economic means of improving their efficiency. Some cities have appreciated this principle as shown in the Lawrence Experiment Station at Boston. But these things cost money and all know what influence "taxes" are made to play in all political campaigns. It appears not unfrequently that the excuse is offered on the part of budget committees, or similar regulating bodies, for not apportioning appropriations, "we can not afford research." No political party could leave a more lasting monument, if it went out of existence, than the establishment of the principle that a great city can not afford not to establish experimental stations. If the leaks are stopped, there will be plenty left not

only to establish bureaus of investigation, but some to save as well

A progressive manufacturer does not hesitate long in substituting more efficient machinery He also knows that his people are more efficient and happier in good sanitary surroundings So, even if the leaks are stopped and the cost of running mounts up, the community is the better able to bear the burden and does it cheerfully The average American doesn't mind paying a suitable price for a satisfactory article, in fact, of late he has become somewhat accustomed to paying a little more than he should

The complications arising from the growth of cities call not only for "the employment of well-trained, tactful, honest, energetic and fearless health officials," but also lays a responsibility upon all forms of educational activity to bring about a "better appreciation by the people at large, of what is conducive and what a menace to public health," and individual safety

In regard to health officials, I can not refrain from expressing an opinion bearing upon the organization of a health department In the first place the head of the health department should be an expert sanitarian and not merely a doctor of medicine, whose training in sanitation has been incidental He should be a specialist in sanitation with the background of a medical doctor Furthermore, the numerous details, especially financial, should not be thrown upon the head any more than the captain of a warship should look after the details of the ship's larder The chief needs every particle of his well-trained brain and energy to deal with the great problems of the city's health He should be provided with a financial coadjutor—a man of absolute rectitude, and as well trained as himself, but along another line —a man who will see that the purchasing power of the city's money is equal to that of a private corporation The terms of office of these directors, technical and financial, should be limited to the period of normal human efficiency, decent pension provisions being made for them when that period shall have ended They would thus be unhampered by any political, religious or social associations, in the conduct of the department I recognize that such a proposition is somewhat radical—in fact in direct opposition to the opinion of some—and sounds a bit utopian, but I am glad to say that my confidence in my fellow man is such that I am willing to give such large powers to him Our democratic government breeds men worthy of such confidence, if it does not, then it is a failure, and we are not willing to acknowledge or to accept that verdict.

CHARLES BASKERVILLE
COLLEGE OF THE CITY OF NEW YORK

SCIENTIFIC NOTES AND NEWS

AT the Minneapolis meeting of the American Association for the Advancement of Science, Dr Charles E Bessey, professor of botany and dean at the University of Nebraska, was elected president for the meeting to be held at Washington, beginning on December 27, 1911 It is planned to hold the meeting of 1912 at Cleveland. The meeting of the association and of the affiliated societies at Minneapolis was in every way successful. The registration of members of the association was 663, which represents an attendance of scientific men about twice as large. Owing to the distant place of meeting, it is necessary to wait until next week for the publication of the report of the general secretary and the addresses of the vice-presidents.

PROFESSOR ALEXANDER SMITH, University of Chicago, was elected president of the American Chemical Society at the Minneapolis meeting.

AT the meeting at Ithaca the following were elected as officers for 1911 of the American

Society of Naturalists: *President,* Professor H. S. Jennings, Johns Hopkins University; *Vice-president,* Dr. Geo H. Shull, Carnegie Institution, *Treasurer,* Professor E. M East, Bussey Institute, *Secretary,* Professor Chas. R Stockard, Cornell Medical School; *additional members of the Executive Committee,* Professor W L Tower, University of Chicago, and Dr B. M. Davis, Cambridge, Mass.

Professor W G. Farlow, of Harvard University, was elected president of the Botanical Society of America at the meeting held last week at Minneapolis.

Dr. W. H. Dall, of the U. S. National Museum, was elected president of the American Paleontological Society at its recent Pittsburgh meeting

The American Psychological Association at the Minneapolis meeting elected Professor C E. Seashore, State University of Iowa, as president, and Professor Walter V Bingham, Dartmouth College, as secretary.

Professor Frederick J. E. Woodbridge, professor of philosophy at Columbia University, has been elected president of the American Philosophical Association and Professor Walter T Marvin, of Rutgers College, vice-president

M Armand Gautier has been elected president of the Paris Academy of Sciences for 1911 M Lippmann becomes vice-president

Dr. Lewis Boss, director of the Dudley Observatory at Albany, and Dr Frederick Kustner, professor of astronomy at Bonn, have been elected corresponding members of the Berlin Academy of Sciences

Dr Richard Hertwig, professor of zoology in the University of Munich, has been made knight of the Maximilian order for art and science.

Professor J H Poynting, F R.S., has been elected a foreign fellow in the Reale Accademia dei Lincei.

Mr. Sydney Chapman, M.Sc., of the University of Manchester, has been appointed a chief assistant in the Royal Observatory, Greenwich.

M. Ernest Fourneau has been elected director of a newly-established laboratory for researches in the chemistry of therapeutics in the Pasteur Institute, Paris.

Dr. Karl Neumann, professor of mathematics in the University of Leipzig, has retired.

Dr John L. Todd, associate professor of parasitology at McGill University, will join the expedition sent by the Liverpool School of Medicine to Gambia, Africa, for the study of tropical diseases.

The movement set on foot by the Liverpool School of Tropical Medicine in commemoration of the work of Dr. J. E Dutton, who lost his life on the Congo through contracting spirillum fever while on the twelfth research expedition of the school in 1905, has now been completed The school has been able to offer Liverpool University £10,000 for the establishment of a chair in tropical entomology. At a meeting of the council of the university it was resolved gratefully to accept the offer.

At the New York Academy of Medicine meeting, December 15, the president, Dr. John A. Wyeth, gave a brief memorial address on the late Dr Robert Koch, honorary fellow of the academy. Dr. S. Adolphus Knopf, who was a student under Dr. Koch, presented a portrait of Dr. Koch.

Dr. Willis G. MacDonald, professor of surgery in Albany Medical College, died on December 30 at the age of forty-seven years.

Dr. Franz Konig, formerly professor of surgery in Gottingen and Berlin and later head of the surgical Hospital of the Charité, Berlin, known for his work in the treatment of articular tuberculosis, died on December 12, at the age of seventy-eight years.

The death is announced of Dr. A. Kraemer, formerly professor of agriculture in the Zurich Polytechnic Institute, at the age of seventy-eight years

The Elizabeth Thompson Science Fund was established by Mrs. Elizabeth Thompson, of Stamford, Conn., "for the advancement and prosecution of scientific research in its broadest sense." The income from this

fund is now available, and the trustees desire to receive applications for appropriations in aid of scientific work. The trustees are disinclined, for the present, to make any grant to meet ordinary expenses of living or to purchase instruments, such as are found commonly in laboratories. Decided preference will be given to applications for small amounts, and grants exceeding $300 will be made only under very exceptional circumstances. Applications for assistance from this fund, in order to receive consideration, *must be accompanied by full information*, especially in regard to the following points (1) Precise amount required. Applicants are reminded that one dollar is approximately equivalent to four English shillings, four German Marks, five French francs, or five Italian lire (2) Exact nature of the investigation proposed. (3) Conditions under which the research is to be prosecuted (4) Manner in which the appropriation asked for is to be expended. All applications should reach, before February 1, 1911, the secretary of the board of trustees, Dr C. S. Minot, Harvard Medical School, Boston, Mass, U. S A.

IT is stated in *Nature* that a prize of 100,000 francs is to be awarded to the inventor of a practical apparatus which will make it possible to save the crews of wrecked submarines, enabling them to regain the surface uninjured The French minister of marine is able to offer the prize, as he has received an anonymous gift from a French lady for the purpose.

MR. THOMAS LUPTON, of Great Britain, solicitor to the Royal Institution, who died on October 30 last, aged 90 years, left £10,000 for the general purposes of that institution.

THE department of zoology and entomology of the Ohio State University has recently received the gift of a fine collection of Lepidoptera from Mrs. Catherine Tallant, of Richmond, Indiana. The collection was made by Mr W. N. Tallant and contains mainly species occurring in central Ohio, especially at Columbus, but has also a number of species from different parts of the United States, and also some fine samples of species occurring in South America, Japan, China, India, Ceylon and Africa. The collection contains about 10,000 specimens in most excellent condition, very beautifully mounted, and many of the species contain very full series, showing variations, etc, which will make them of special value for scientific study They are, for the most part, carefully identified and will be kept under the name of the "Tallant Collection" Taken with the other collections in Lepidoptera, the collection of Odonata left by Professor Kellicott, and those in various groups which have been accumulated by the efforts of the members of the department, the university is now provided with excellent series of insects, including representatives in all the different orders The total number of specimens in all orders probably approaches close to 100,000.

THE expedition sent by the Carnegie Institution of Washington for geologic exploration in China in 1903–04, in charge of Dr. Bailey Willis, secured a number of large negatives of Chinese scenes representing the scenery; the geological conditions, particularly of loess landscapes, and also of Chinese buildings, monuments and people. The route of the expedition through the provinces of Chili, Shansi and Shensi, led through the loess district and some remote mountain regions of great interest and scenic beauty. This collection of photographs has been placed on file with the Smithsonian Institution and copies may be had for educational purposes by application to the secretary of the institution and payment of costs.

TRINITY COLLEGE, Hartford, Conn., has retained the Ralph B. Carter Company, of 50 Church Street, New York, to install a circulation sea-water system in the five marine tanks in Boardman Hall, similar to the one which they placed in the aquaria house at Princeton. Hard rubber piping and valves are used to convey the sea-water from cedarwood tanks, and return the water to the reservoir, also of cedar, by way of a sand filter. The water will pass through a bronze motor-driven compressor

into an air reservoir where aeration will take place and air and water together will be pumped through the pipes to the aquaria, thus differing from the Princeton system where a column of air is forced against the water in the pipes and the water does not enter the pump The tanks may be converted immediately into fresh-water tanks, whenever this is desired.

THE subjects and dates of the lectures to be delivered before Easter at the Friday evening meetings of the Royal Institution of Great Britain are as follows January 20, Sir J Dewar, "Chemical Change at Low Temperatures", January 27, Professor W H Bragg, "Radioactivity as a Kinetic Theory of a Fourth State of Matter", February 3, Mr A E Shipley, "Grouse Disease"; February 10, Mr S Colvin, "Stevenson"; February 17, Professor H E Armstrong, "Digestive Activity", February 24, Professor Jean Perrin, "Mouvement Brownien et Realité Moleculaire" (in French), March 3, Professor Karl Pearson, "The Inadequacy of Causation in Modern Science", March 17, Mr J H Balfour-Browne, K C, "Water Supply", March 24, Sir D Gill, "The Sidereal Universe", March 31, Professor H S Hele-Shaw, "Traveling at High Speeds on the Surface of the Earth and Above It", April 7, Sir J J Thomson, "A New Method of Chemical Analysis" A course of Christmas lectures on "Sound Musical and Non-musical" will be given by Professor Silvanus P. Thompson in the afternoons of December 29 and 31 and January 3, 5, 7 and 10

UNIVERSITY AND EDUCATIONAL NEWS

COMMEMORATIVE exercises in celebration of the completion of the first twenty-five years of the work of the Carnegie Laboratory of New York University, and of the opening of the Carnegie laboratory extension, will be held on the afternoon of January 10. Addresses will be made by Mr Andrew Carnegie, Dr. William H Welch, Dr Henry S. Pritchett, Dr Hermann M. Biggs and Mr Jerome D Greene.

THE fifth congress of the American School Hygiene Association will be held at the Academy of Medicine in New York City on the second, third and fourth of February A tentative program includes papers by Lyman A. Best, William H Allen, Dr. S W. Newmayer, Dr Myles Standish, Dr. Woods Hutchinson, Dr Thomas F. Harrington, Dr W. S. Cornell, W E Watt, Dr Arthur T Cabot, Dr Luther H Gulick, Leonard P. Ayres, Dr Helen MacMurchy, Professor William H Burnham and Dr John J Croner.

DURING the thanksgiving recess at the University of Illinois, a party of electrical engineering students and of architectural students took a trip of inspection to various points in the vicinity which are of especial interest to engineers The electrical students visited the Quarry Street power station, the steel works at Gary and the works of the Allis-Chalmers Company at Milwaukee. The architectural students visited various buildings in Chicago and inspected the plant of the Northwestern Terra Cotta and Tile Company

Professor C. S. Sherrington, F.R.S., of Liverpool, and Dr. William Bulloch, director of the Bacteriological Laboratory of the London Hospital Medical School, were appointed members of the advisory board of the Beit Memorial Fellowships for Medical Research The next election of fellows will be held in December, 1911 The last date for receiving applications from the colonies and abroad is October 1, 1911, from Great Britain and Ireland November 1, 1911. Communications should be addressed to the Hon. Secretary, Beit Memorial Fellowships for Medical Research, 35, Clarges Street, London, W.

IN behalf of a donor who withholds his name, Mr George L Rives, chairman of the trustees of Columbia University, and Mr Robert W. DeForest, president of the board of managers of the Presbyterian Hospital, announce that $1,300,000 has been pledged for the perfection of an affiliation between the hospital and the College of Physicians and Surgeons of the University The gift comes through Mr. Edward S. Harkness, of New York and Cleveland, who gives $300,000 for a surgical pavilion and a laboratory for research work. Several conditions are named, the two

most important being: (1) That the hospital shall admit to the wards students of the medical schools to the extent and in the manner permitted by the most approved practise. (2) That the educational institution concerned may make nominations to all positions on the hospital staff, medical, surgical and special.

THE completion of the fund of $750,000 for the Johns Hopkins University is announced. This insures the payment to the fund of a further $250,000 offered conditionally in February of last year by the General Education Board.

BY the will of Mrs. Martin Kellogg, Yale University receives a bequest of $50,000 from the estate of the late Martin Kellogg, who was formerly president of the University of California.

MR. H. J. PRIESTLEY, M.A., assistant lecturer in mathematics at the University of Manchester, has been appointed professor of mathematics and physics in the newly-constituted University of Queensland.

DISCUSSION AND CORRESPONDENCE

SYMBOLS IN ZOOLOGICAL NOMENCLATURE

PROFESSOR NEEDHAM'S proposal[1] of a plan for practical nomenclature deserves more attention than has yet been given it publicly. To be sure, our energetic friend Professor Cockerell has published a brief destructive critique[2] based on personal opinion as to what can be most easily retained by the memory, and on sentiment. As to the former, one might differ from him in individual cases, or might justly observe that memory is not the only factor involved in Professor Needham's proposal. So far as sentiment goes the incongruity and falsity of many names will make as good an argument on the other side of the question, while the colorless number adapts itself far better to changing interpretations with the progress of science than any word with its fixed relation to ideas. Nor can I believe that it is any part of scientific nomenclature to "call up pleasanter [philological] thoughts." It certainly is worth while to have the great names of the past brought to our attention, but such men are in our thoughts constantly not because they have named a few species more or less, but because they have made real contributions to the progress of science. And what shall one say of the constant burdensome recurrence in systematic work of the names of the unknown, of those who have torn down the good work of their associates and have left the roadway of science rocky with synonyms, errors in determination and description, false statements and careless records, misspellings and misquotations. It is these rocks in the way that make the pilgrim to-day toil wearily up the height more conscious of the obstacles such men have left than of the substantial roadway the real workers have constructed.

But to my mind all of this fails to reach the heart of the problem or in any way to affect the fundamental contentions urged by Professor Needham. For this reason I am anxious to aid if possible in directing attention to the real questions at issue and the probable lines for their successful solution.

The history of all science shows intercurrent tendencies towards simplification and complication. The data already established are reduced to greater simplicity in expression and the new relations that are demonstrated involve them at the same time in constantly increasing complexity. That simplification in terminology is a real tendency is apparent to every one who studies the history of zoology and compares the long and involved circumlocutions of early writers with the more precise designations of to-day. Hand in hand with this simplification in form goes a movement towards standardization in use and meaning which finds its expression in modern terminology. The term becomes more precise as it becomes more limited and because its use is limited.

The history of zoology does not in this respect differ from the past of other sciences and yet the comparison shows that some other sciences have progressed further along this

[1] SCIENCE, September 2, 1910, pp. 295–300.

[2] SCIENCE, September 30, 1910, p. 428.

line of development than zoology has yet gone. Such a simplification by the employment of symbols has become thoroughly incorporated into the substance of some sciences and is proposed for introduction into others An examination of these conditions shows some interesting and in my opinion valuable considerations for this discussion

Probably because numbers were the basis of mathematics the origin of the science is often said to date from the invention of numbers. But even with that it may be noted that the symbols were not in all cases identical and in one system Roman letters were employed, whereas another used Arabic numerals for the same general purpose Nor can one well doubt the superiority of the Arabic notation over the Roman even if sentimental grounds lead one to prefer the classical to the Moorish civilization in laws, government or other social conditions Probably mathematics represents the most highly developed of all sciences and the modern mathematician is not deterred from the use of symbols by any danger of misprinting, confusion, error of memory or other similar objection, real though each of them is in this case also.

The case of chemistry is even more enlightening because the introduction and universal use of symbols is of comparatively recent date. One does not have to seek far to find arguments against the use of symbols for the designation of chemical elements which read strikingly like the objections of Professor Cockerell to the plan which Professor Needham advocates Errors do occur in chemical literature, proofreading is far more difficult because of the numerous easily confused symbols in use to-day and the abandonment of those quaint old names which disclose some of the secrets of the alchemist and of the mystic age of chemistry, was a real sentimental loss Yet I doubt if any one could now be found who would seriously contend that we should return to the presymbolic days even if it were possible to express modern chemical work in ancient form. Simplification through the use of symbols has come to stay in chemistry as in mathematics.

It is no argument whatever against the general proposal to introduce some such system into biological sciences to say that the latter are less precise, that their units are more numerous and more complicated than those of mathematics or chemistry. If the problem had been as simple it would have been solved as easily as were the others The delay in reaching any solution indicates the existence of difficulties but does not afford any basis for rejecting efforts to solve the problem or for characterizing the problem as insoluble along this line The greater complications of biology make its development slower because they demand for their consideration and analysis a more highly organized general scientific foundation and a more highly trained body of scientific workers The solution may not come in our time, but it will surely come some day.

But other sciences also are looking for possibilities of simplifying and of standardizing their forms of expression in the manner so successfully adopted by chemistry. One example of most recent date may suffice to show the tendency. This is taken from what may be regarded as the most recent addition to the circle of sciences, geography. In an address before the Geographical Section of the British Association at Sheffield this year, the brilliant young Oxford geographer, A. J. Herbertson,[3] dwells upon this matter, saying in introduction, "I have long thought that we shall be driven to some notation analogous to that of the chemists." After suggesting a possible scheme for consideration he adds: "This is the roughest suggestion, but it shows how we could . . . No doubt there would be many discussions . . . But after all these discussions would be more profitable than quarrels as to which descriptive term, or place name or local usage should be adopted to distinguish it."

With only minor changes in phraseology this description of dangers and profitless discussions which geography should avoid portrays actual conditions in the zoological field.

[3] SCIENCE, November 25, 1910, p. 745.

Zoological nomenclature has received heroic treatment during the past ten or fifteen years The difficulties which had arisen in the natural course of development under the Linnæan system had led to numerous isolated efforts for their correction until finally an attempt has been made to remedy the evils under the control of a central organization which has been so firmly established by zoologists as to be at present beyond their control and swayed by laws alone. Yet even such an autocratic and omnipotent body has not succeeded in doing more than increasing the difficulties of the situation It really seems as if the problem requires more radical measures for its solution The present plan of organization is incapable of coping with the complications which have arisen in the rapid expansion of biological knowledge during the last half century. Personally, I am convinced that the Linnæan system offers no probability of meeting the situation. Of this there may be some question, but there is abundant evidence to show that the existing zoological nomenclature is meeting with wide-spread criticism and does not command the support to be expected of so fundamental a system. Indirect but weighty evidence of this may be found in the fact that the use of common names is increasing and that a larger proportion of biological workers than ever before are avowedly indifferent to the use of technically correct scientific names.

Present conditions are denominated unsatisfactory by able men in many places and in diverse special lines of work in the general field. The most important general criticisms of the existing conditions may be stated briefly as follows:

1. *Lack of Stability*.—Present nomenclature by law depends upon the accuracy of the past and upon the completeness of our knowledge concerning its work. At any time demonstration of an error in statement or of an omission in the references to previous work may overturn a name or series of names and throw all the literature on the group into confusion. New laws and new rulings are made with the same result, for in our effort to out-Herod Herod we go further than the law, that most conservative of professions, has ever gone We make and enforce *ex post facto* laws which upset the established practise of a century.

2 *Overemphasis upon Trivial Features*.—Page-long discussions recur constantly on the acceptance of *A*'s name or *B*'s name and both sides argue with apparent justice and at interminable length Articles follow hard on each other's heels dealing exclusively with the spelling of names: Shall it be *somum* or *somai*? Shall one write *nni* or *nii*? And the questions are never decided, for even the high priests of the movement differ in their views and their practises, and the great majority of biological workers pay little attention to the strife because they feel the issues are trivial. Now the real meat of the question is the thing and not its name And all this energy devoted to a study of the animal itself would yield much of value to science. The workman does not care whether *A* or *B* gives him his tools, he wants a tool and wants it sharp, because he wants to do work with it. He is rightly impatient of so much hair splitting to so little purpose, but he does look forward to the time when in some way this energy may be diverted into productive channels.

3. *Exaltation of Error*.—If a tyro commits an error, if a neophyte goes astray or makes a foolish move, we are accustomed in science otherwise to consign his work to kindly oblivion, but in nomenclature this may not be. The skeleton of his misbirth must be hung in the public hall of the systematic museum, to dangle its misshapen bones before both students and visitors for all time. There is no other option possible to-day under the laws of nomenclature. A mistake once incorporated in the literature of biology must forever remain there, even though apparent to the man of education at a glance The most conservative theologian would hesitate to support such an inflexible demand for the maintenance of the past, errors and all. And the very fact that able and zealous advocates of present nomenclature contend there is no other way under the present system compels

the conclusion that this system is insufficient for the needs of a science which seeks to eliminate error and to establish truth.

4 *Multiplication of Complications*—No one can doubt that the complexity of zoological nomenclature has increased enormously within very recent years Furthermore, no one will deny that much of this increase is due to the expansion in our knowledge of the biological world and its interrelations This natural growth in complexity is as welcome as it is inevitable, but if real progress is to be achieved it must be accompanied by a perfection and simplification of the machinery of control and of investigation in which a prominent element is the systematic nomenclature of the subject Now there is reason to believe that the system in use has become unnecessarily intricate, that its parts are involved by the nature of the case in ways such as to create grave difficulties for the ordinary worker These difficulties are certainly greater to-day than they were twenty years ago and this result has been produced by the changes and complications incident to the new legislation in the subject during very recent years Such changes may have been wise and necessary from the legal standpoint, they may be perfectly in line with the natural development of the present system But that only strengthens my contention that zoology must look for a better system, must seek a way of escape along an entirely new line. I am aware also that these changes meet the approval of those who have devoted much time to the study of taxonomy and that they do not regard the complications as hindrances to progress No doubt from their point of view this is true, but there is another aspect of the question which deserves careful examination

To the skilled systematist, thoroughly acquainted with his own groups, confident, accurate, critical, these difficulties constitute intellectual stimuli rather than stumbling blocks He follows the changes in names with delight in the history of the science that they portray. Outside his own corner of the field he often does not care to go, or if he wanders it is not so far afield that he is at a loss to find the necessary help to keep him in the path But to the general worker this constant shifting constitutes a real burden that retards his progress and reduces the efficiency of his work. This is, however, not the most serious feature of the case

To the general public even in the educated world scientific names will perhaps remain as they unfortunately now are regarded, "beyond the powers of ordinary mortals," and birds and beasts, insects and shells, will continue to be called by their popular names because the latter are not only simpler, but also do not change from day to day But to the neophyte who hesitates on the threshold of the science, uncertain whether he shall enter or who later pauses before he essays to mount to higher levels in the fields of our elysium, the difficulties which our present nomenclature sets in his path are at best disheartening He would read of the great work of the past and know its relation with that of the present But you must tell him that *Amphioxus* is not such but *Branchiostoma,* that *Holothuria* is not an echinoderm, that even *Amœba* to-day is *Chaos!*—and a multitude more changes which confuse his mind and dull his enthusiasm He wants to study life, not letters But at the very start of his work he is forced to violate that canon of accuracy which is the foundation of science or to assume a burden that wastes his energy in a vain effort to keep up with the latest revisions of nomenclature. Like Sindbad the Sailor, he struggles along with this Old Man of the Sea on his back until he decides to be quit of his burden, and without openly indicating his purpose, contrives to wander off with the morphologists or biologists, leaving nomenclature behind.

Now these multifarious complications are the necessary and logical consequences of the system of laws which zoologists themselves have adopted and as such are unavoidable in the opinion of the expert legalist. The natural reply to such a dictum is then let us follow the promptings of our scientific consciences and devise some better system. Why should we not find a simpler and effective

method of designation in a system of symbols such as other sciences have found? I am not in sympathy with those who look for relief in a laxer more open administration of the present system. Such a line of action does not seem to me likely to prove either effective or legitimate.

This rigor in systematic nomenclature is a natural reaction from the free and easy methods which have prevailed in the past. Biological science even to-day publishes loose, inaccurate statements in research contributions which would be laughed out of court in physics or chemistry, to say nothing of mathematics or astronomy. It is necessary that some reform be undertaken, that our branch of science approach more closely to the precision in observation and experiment, in record and discussion that characterizes older sciences. The natural lack of fixity in biological phenomena has been utilized to excuse a lack of precision in method and investigation which must be corrected. One effort to reach a more justifiable basis is seen in the recent development of statistical work, and in the publication of definite numerical results rather than merely generalizations in connection with experimental work, in the effort to control more accurately and state more precisely the conditions of such experimentation and to analyze more closely the results obtained. In such lines zoology has achieved wonderful progress in the last twenty years or even less.

The same influences will lead to a reform of our system and, following the lead of other sciences, such a reform is likely to be accompanied by the simplification which is associated with the utilization of symbols. The far-seeing biologist should be on the watch for a plan which promises some measure of success in this line, he should welcome all reasonable attempts at the solution of the problem. Of course he will not reject any and all systems because they are new departures, and yet he should not fail to subject each to careful consideration because it may seem to be inadequate or only partially worked out. Out of such careful discussion will come the longed-for result in a workable form. But the system itself will represent contributions from many sources.

I confess that Professor Needham's plan seems to me at most only a partial solution of the problem. Even as such it may prove to be of great value and it is to be hoped that biological workers may be willing to try it on various groups in diverse portions of the field and may then report on their results. Better still if it could be subjected to a trial by some recognized society or institution with a view to testing thoroughly its character. It would be valuable to compare it carefully with the much more complex system proposed some years ago by Tornier[4] which seems to have attracted no attention, although it was a most ingenious and original means of formulating a symbolism for zoological nomenclature. While this system was much more complex and covered not only species as proposed by Professor Needham's plan, but also genera, and indicated the precise place in class, order and family occupied by each genus and species, yet apparently the symbol used for a given form would not be permanent and independent of changing views regarding the position and relationship of genera and higher groups. This lack of stability would be a serious, if not fatal, objection to the introduction of a new system planned to correct precisely the same defect in the old.

HENRY B. WARD

ZOOLOGICAL LABORATORY,
UNIVERSITY OF ILLINOIS

BOTANICAL EVIDENCE OF COASTAL SUBSIDENCE

IN a recent article[1] Professor D. W. Johnson calls attention to certain conditions at Scituate, Mass., which are there responsible for a fictitious appearance of coastal subsidence. During the "Portland Storm" of 1898 the bar was broken which at that locality almost separates the North River marshes and bay from the ocean, with the result that the high tide level on the marshes is now from one to several feet higher than it was then.

[4] *Zool. Anz.*, Vol. 21, p. 575, October 24, 1898.

[1] SCIENCE, N. S., XXXII., 1910, p. 721.

Trees surrounding the marsh have been killed and are now standing among salt marsh grasses. Since breaches in bars, widening of tidal inlets and other shore-line changes may cause local fluctuations of a number of feet in the high-tide surface, Professor Johnson hastily concludes that no evidence of recent subsidence on the New England coast thus far presented can be considered satisfactory.

It is the mean sea level, rather than the irregular and changeable high-tide surface, which is most important in discussions of coastal subsidence. Below mean sea level the salt-marsh builders, *Spartina glabra* and *Spartina patens*, can not live. As a matter of fact *Spartina patens*, by far the more important of the two plants, seems to occur in significant amount only within a vertical range of about two feet. It builds its turf up to mean high-tide level. Above this level it is for the most part replaced by other plants, notably by *Juncus Gerardi* and various species of *Scirpus*. We may, therefore, regard any thickness of *Spartina patens* turf greater than two feet as a measure of change in high-tide level. If such turf extends to mean sea level, or below it, the evidence that subsidence has taken place is indubitable. If a deep turf is of uniform texture throughout, a strong presumption is created that subsidence has continued uniformly to the present time. *Spartina patens* turf lies below mean sea level at many places in the vicinity of Boston, as, for example, near the mouth of the Saugus River, where it forms a homogeneous stratum to a depth more than ten feet below high-tide level. The geological significance of turf formation by *Spartina patens* has been pointed out by Professor C. A. Davis,[2] of the Bureau of Mines. He presents substantial evidence that coastal subsidence is now going on—evidence to which the hypothesis of a fluctuating high-tide level has no possible application.

Aside from the value of the salt marsh deposits themselves as indicating subsidence, there is still another type of botanical evidence which Professor Johnson should not so lightly have disregarded. In certain cases where fresh water peat is found below mean sea level, in obviously undisturbed relationship to the substratum, whether or not the deposits have ever been invaded by the sea, we have incontrovertible evidence of subsidence. The full argument in support of this statement has been published elsewhere,[3] but may be briefly reviewed here.

Peat deposits are of two main types, depending upon the relation of the water table to the ground surface in the depression in which they are formed. In the first type the depression contains a pond or other body of water, so that the peat is derived from aquatic plants and from the surface of the water, through the agency of mat-forming plants. If the water in such a depression were fresh, a mat might be formed at or slightly above sea level, and fresh-water peat of this type would then be laid down below sea level. If the ocean should break into such a bog it is conceivable that the mat might settle considerably and then be covered by salt-marsh deposits. Such a condition I have never seen.

The second type of peat deposit is built up from the ground by successive elevations of the water table, as we know from the character of the plant remains which it contains. At every stage of growth its surface has very nearly coincided with the ground water level. Since in coastal Massachusetts the water table is never lower than sea level, a bog of this type, if its bottom is lower than mean sea level, must of necessity be interpreted as a record of subsidence.

There is a locality at Quamquisset Harbor, on the coast of Buzzard's Bay, where the sea has cut into a *Chamaecyparis* bog. At the water's edge a sounding showed uniform peat, containing *Chamaecyparis* wood, to a depth of fourteen feet below mean sea level. The sand bottom of the deposit had not been disturbed by under-cutting. At the point where this sounding was made, there were salt-marsh deposits in a thin layer overlying the peat,

[2] "Salt Marsh Formation near Boston and its Geological Significance," *Economic Geology*, V, 1910, p. 623.

[3] "The Submarine Chamaecyparis Bog at Woods Hole, Mass.," *Rhodora*, XI., 1909, p. 221.

but further inland the *Chamaecyparis-Sphagnum* peat was still forming, at an elevation perhaps three feet above high-tide level, and soundings showed that the deposit was uniform from top to bottom. Within a very few feet of the seaward edge of the marsh there are still two or three small stumps which project several inches above the *Spartina patens* turf which has grown up around them. These constitute a strong argument that subsidence is still going on. If there had been no subsidence for 3,000 years, as Professor Johnson thinks likely,[4] these little stumps would surely have rotted away by this time!

The Coast and Geodetic Survey has furnished data regarding the tides in Quamquisset Harbor. Spring high water is 2.4 feet above mean sea level. Mean high water is 2.0 feet above mean sea level. The highest tides observed were 3.0 feet above mean sea level. These tides at Quamquisset are so low that Professor Johnson's hypothesis of a fluctuating high-tide level can not possibly be invoked in explanation of the submarine peat beds.

After examining one locality where salt-marsh plants have invaded a fresh-water vegetation under conditions certainly far from typical, and where all of the fresh-water remains are found at extreme high tide, Professor Johnson has ventured to characterize all the evidence which has been offered for recent subsidence as inconclusive. As a matter of fact his hypothesis has no bearing whatever on most of the evidence which has been offered.

H. H. BARTLETT

BETHESDA, MD.

FACULTY OR PRESIDENT?

THE discussion of the merits of control by the faculty or by the president in any educational institution, which has been presented from time to time in SCIENCE, was continued by some references in Professor Cattell's article in the issue for November 11, and by a short paragraph in the abstract of President Schurman's annual report in the following number. There is still another angle from which the matter may be viewed.

The student body in a college, or university, is a comparatively constant quantity. The great majority of students spend the four years from about eighteen to twenty-two in the institution of their choice. The average age of the student body, taken as a whole, would, therefore, be slightly under twenty, owing to the somewhat greater numbers in the freshman and sophomore classes. Whatever fluctuations there might be from year to year, in consequence of an exceptionally large or surprisingly small entering class, or because an unusually large number from the upper classes turned to professional work before graduation, they would be within very narrow limits, so narrow, indeed, that the entire body of students might be regarded as an individual not quite twenty or just over twenty years of age. The same would be true of a university with the various professional schools and the liberal arts or undergraduate department, although the average would probably be three or four years higher. The student body itself, none the less, would be comparatively stable.

If we turn our attention to the faculty, we find another fairly constant quantity. Since the retiring age is somewhere about sixty-five or seventy—it might be a little over or a little under—and since the youngest instructors are just out of college, the average age of a faculty would be somewhere between forty and forty-five, as a rough estimate. If there should be an unusually large number of young instructors, or an extra large number of elderly professors, then the average age would be lowered or raised correspondingly, but in either case it would not be far from the age mentioned above, and from year to year the fluctuations would be within rather narrow limits, so that there would be a fairly stable body to exercise control of whatever sort. In those institutions in which the youngest instructors have practically no voice in the administration, the average age would be raised, but the faculty would retain its characteristic of a constant quantity.

When the problem is presented in this way,

[4] SCIENCE, N. S., XXXII., 1910, p. 709.

we have two constants sustaining a constant relation to each other. They are not so far apart, too, in the matter of age, but that each may understand the other. The relation is essentially that of parent and child. The student body may be regarded as of a healthily radical temper of mind, and the faculty as healthily conservative Sociologists maintain that both radicals and conservatives need to be united in a community, with the center of gravity slightly on the radical side, if that community is to be healthily progressive With the faculty and students viewed as above, the conditions are right for a sanely progressive institution, since we may, perhaps, assume that the larger size of the student body would give the desired overplus of radicalness At any rate, there would be a steadiness of control and of purpose, and a sufficiency of sympathy to insure hearty cooperation and splendid scholarly results.

When, however, we consider the matter from the side of the one-man power, whether that man be president, or some other official with the bit in his teeth, the conditions do not seem to be so favorable for desirable results If the president be young—we will say thirty years of age, as sometimes happens—the center of gravity is too much upon the radical side, when the same man gets to be sixty-five or seventy, provided he stays that long, or has an elderly successor, the balance shifts too much in the other direction It is true, of course, that there are conservative young men and progressive old men, but, none the less, the fluctuations in the age of the controlling official constitute a variable more likely than not to be a disturbing factor in the otherwise constant and harmonious relation between faculty and students In the case of the elderly man being in supreme control, the relation of parent to child will be superseded by that of grandparent to grandchild, with consequent ready indulgence or excessive rigor The latter is, perhaps, the more likely, since the nervous strain develops irritability and the exercise of power breeds arbitrariness.

When the problem is viewed from this angle, the wise policy would seem to be to have faculty control in an educational institution, rather than that any one man should reign supreme.

THE MATTER OF UNIVERSITY FELLOWSHIPS

TO THE EDITOR OF SCIENCE The address of Dr Jordan as retiring president of the American Association for the Advancement of Science, printed in your issue for December 30, contains many things that will appeal to every one as both true and timely, there is the more reason to regret that some things are said against which, I think, protest should be made I do not believe it is true, as he seems to think, that the system of university fellowships is a powerful influence working against our best university ideals Dr Jordan seems to me to have lost sight of some very important facts when he stigmatizes the fellowship system as one "whereby men are hired to work under men they do not care for and along lines which lead not to the truth they love, but to a degree and a career." I am sure he does injustice when he asserts that "The embryo professor asks for his training not the man of genius who will make him over after his kind, but the university which will pay his expenses while he goes on to qualify for an instructor's position"

All will admit that the fellowship system has not always been wisely administered, that evils have crept into the practise of some institutions, that these ought to be (I think can be) corrected We have all had experience of the man whose letter expresses a desire to work at our particular university and inquires, "What inducements can you offer me to come?" Undeniably, universities are themselves responsible in some measure for making possible such an attitude; but it would seem that only a particularly unlucky experience could make one regard this as typical of the graduate student in general

Dr Jordan's ideal university is one where advanced students are "gathered around a man they love, and from whose methods and

enthusiasm the young men go away to be like centers of enthusiasm for others" It is a high and noble ideal, and one towards which we are all most heartily ready to strive; but it is rather difficult to follow the logic of the conclusion that a fellowship system tends to destroy this ideal It would be invidious to refer to particular men or universities had not Dr. Jordan himself set the example by naming, among others, four eminent teachers at one university who exemplify the ideal he has in mind It is entirely true that these men drew students about them by the force of their ability and personality, but is it not also true that the university which placed them on its faculty did more than any other American university had previously done, by a system of wisely administered fellowships, to make such a gathering of students possible? It was my own good fortune to be one of those students, and I count it not only as a lasting honor but as the most important turning point in my life that appointment to a university fellowship enabled me to place myself under the inspiring influence of three of the four men whom Dr Jordan names I am sure that many others whose after lives have been given to teaching and research can bear like witness

Dr. Jordan argues that it would be a difficult task to produce a Darwin, given the raw material, "if a fellowship of $500 had drawn him to a laboratory of some lesser plodder" But what does this prove if not the desirability of trying to widen the usefulness of the gifted teacher by making it easier to gather students of promise about him, and by helping such students as well as we can to the opportunity they seek? Happily for science, the circumstances of the youthful Darwin placed him beyond the need of such aid He was free to "walk with Henslow" (to quote Dr Jordan's own happy phrase), but had it been otherwise, who can estimate the value to the world of a helping hand to Darwin at a critical moment? We are sometimes told that fellowships tend to "pauperize" students. I do not believe it. All honor to the man who works his own way through college and university life. But the years of graduate study, perhaps above all others, ought to be a time of undisturbed and unremitting devotion to one's chosen work The man whose ability and scholarship have proved him worthy to enjoy the privilege of at least one such year is in no danger of pauperization by the fellowship that gives him the opportunity If he has been well chosen, his stipend is as well earned as that of any officer of the university. In my belief the university makes no better investment than the $500 a year that enables the man of talent, but of limited means, to carry on his work, and the example and influence of such men among the body of graduate students constitute one of the best assets of the university

SCIENTIFIC BOOKS

A Text-book of Botany for Colleges and Universities, by members of the botanical staff of the University of Chicago, JOHN MERLE COULTER, Ph D, Professor of Plant Morphology, CHARLES REID BARNES, Ph D, late Professor of Plant Physiology; HENRY CHANDLER COWLES, Ph D, Professor Plant Ecology. Vol I, Morphology and Physiology New York, Cincinnati and Chicago, American Book Company 8vo Pp viii + 484 + 12

When Strasburger with his colleagues in the University of Bonn brought out a textbook of botany it was promptly named the "Bonn Text-book," following which precedent it has been suggested that the book before us should be named the "Chicago Text-book" And this American book promises to be a worthy rival of its German predecessor, which no doubt it will replace in many college and university classes. When complete, the book will include morphology, physiology and ecology, but for some reason not stated in the preface, only the first and second are now published. Probably that will follow before long, as some reference is made in the preface to "Part III." as at least partly prepared for publication.

The book is doubly interesting in that it

presents a certain amount of organized information in regard to a portion of the science of botany, and also that it gives us the result of ten years of experience in working out the method of undergraduate instruction in botany in one of the foremost botanical laboratories in the country. The authors here endeavor to present "the fundamental facts and principles of the science," and they hold that these should precede the work of most other subdivisions of botanical investigation. Thus they point out that "a study of the very important subject of plant pathology must presuppose the fundamentals of morphology and physiology, paleobotany is, in part, the application of morphology and ecology to fossil plants, and scientific plant breeding rests upon the foundations laid by morphology, physiology and ecology"

Here we have then an expression of the opinion of three eminent teachers as to what should be the "content" of botanical instruction, and its proper sequence, and it is that the structure of plants must be presented first in an orderly sequence from the lower to the higher forms, and that then the activities of plants must be considered, while the relations of plants to one another and to their physical environment may well come after form and function have been pretty fully considered. Then when these fundamental subjects have been pretty well mastered the student is ready to go forward into pathology, paleobotany, plant breeding, etc The book is thus a contribution to botanical pedagogy. This aspect of the book is, we believe, most important at this time when some teachers have the notion that it makes little difference in what order the subdivisions of botany are taken up.

The morphological part plunges at once into a study of the Thallophytes, taking in succession (1) Myxomycetes, (2) Schizophytes, (3) Algæ, (4) Fungi, followed by Bryophytes, Pteridophytes and Spermatophytes, and a suggestive chapter entitled "Organic Evolution" The treatment is admirable, and the more than six hundred illustrations make this one of the most satisfactory morphological texts with which we are acquainted The student who runs up through the vegetable kingdom in the sequence here given can not fail to secure a clear conception of its general plan, as well as of its probable mode of evolution.

The second part, devoted to Physiology, takes up the subject under five heads, viz., (I) the material income of plants, (II) the material outgo of plants, (III) nutrition, (IV.) destructive metabolism, (V.) growth and movement The treatment here is as satisfactory as in Part I., and as we read the lucid sentences we are reminded forcibly of the great loss suffered by botanical science through the death of Professor Barnes We can not refrain from quoting a few sentences, both for the substance and as illustrating the forcible presentation.

> Transpiration, far from being a function of plants, is an unavoidable danger That it is a danger, a real menace to life, is almost a matter of common observation Millions of plants perish annually because the outgo of water is greater than the income A loose soil and an exposed situation, sudden extreme evaporation due to a hot dry wind and a blazing sun, or prolonged drought, are causes of death too well known to farmers in some regions Scarcely a plant escapes the loss of some parts by reason of shortage in the water supply, and in temperate regions, with the average rainfall (say 100 cm annually), few plants attain the development of which they are capable with a larger water supply The luxuriant weed of well watered ground compared with the same weed, meager and dwarfed on the dry wayside, illustrates what a menace to life and vigor is the evaporation from plants.

It is greatly to be deplored that the facile hand that penned, and the active and original mind that framed such vigorous and lucid sentences are forever stilled, and that the work here so well begun must stop, or be carried forward by others. And who is there who can take the place of Barnes?

CHARLES E. BESSEY
THE UNIVERSITY OF NEBRASKA

Attention and Interest: A Study in Psychology and Education. By FELIX ARNOLD, Ph.D. New York, The Macmillan Company.

In this volume Dr Arnold presents the results of a study of the practical aspect of his problem. "The present essay on the psychology of Attention and Interest," says the writer, "is an attempt to classify and arrange the many facts that have been brought to light by numerous experiments in the psychological laboratories" In order to allow of the fullest review of such facts the conception of attention has been made as simple as possible; as developed in the Introduction, attention is the correlative of the development of an "object" in consciousness The appearance of such an object of consciousness is not incidental to mental activity; in all developed consciousness it is its characteristic form The problem of the essay is an inquiry into the history and values of this characteristic activity of mind Attention and interest are therefore considered in their intrinsic relations as systems of ideal elements, in their conditions as phases of a teleological existence, and in their relation to concomitant or consequent physical changes

The writer's interest is thus not in giving a logical formulation to the conception of these phases of mental activity, nor in seeking the inner distinctions upon which their separation as ideal forms is based. He therefore systematically subordinates the guiding conceptions which may have lain back of an individual investigation and ignores the theoretical formulation to which it may have led, in order to utilize all established facts in the given field. "I have felt myself bound," Dr. Arnold says, "not to uphold any special theory or school, but to present the facts as they seem to be" With reference to all purely psychological problems the book may therefore be called selective; it represents a sifting of the literature with a view to presenting in a succinct review the ascertained facts concerning attention and interest, in their manifold connections, which are of importance to the teacher. As the writer's motive is not critical but practical, and as the aim is to make the reader acquainted with those special aspects of the subject which are of value in connection with the problems of the school-room, the discussion falls into two parts, first, the presentation of the results of experimentation, and second, the application of these results to school-room practise. The résumé of literature is given separately for each of the two topics, but the applications are considered in a single discussion The book thus falls into three parts: (I.) Attention, (II.) Interest, (III.) Education In dealing with each topic the writer simplifies the discussion by separating his description of the facts from their explanatory, developmental and illustrative treatments, which are considered in separate sections.

By its aim the book disarms criticism for any lack of rigid psychological criteria in the matters of definition and limitation of discussion, since it is a summary of results determined primarily by the needs of the teacher Though the psychologist may rightly demand a definition of attention, or of interest, in such terms as to limit the view to phenomena of consciousness alone, the teacher must take into account the whole psychophysical situation in which the child is placed if he aspires to stimulate his attention or direct his interest He must study the effects of extraneous stimulation, fatigue, nutritive condition and motor control, as well as those of practise, rest, age, mental development and the like. The mind's activities are both physically and historically conditioned, and their supplementation or ideal control is made possible by this correlation alone. From the teacher's standpoint it is just these extrinsic features of attention and interest—with which Dr. Arnold's book so largely deals—which are of real importance. The analysis of inner distinctions and correlations in the ideal systems themselves which may be called their intrinsic features are, as Herbart long ago pointed out, least of all to be considered in such a connection, though they may constitute the primary phenomenon for the introspective psychologist. Dr. Arnold's summary of these objective stimuli to interest, and of the physical conditions and manifestations of attention is full and well presented. In the opinion of the reviewer it is here that the

value of the book lies. The varied information which it brings together in a compendious form will be found useful by the psychological student and lecturer as well as by the teacher.

When the writer undertakes to bring his materials together in a systematic review the result is less satisfactory. It is, of course, impossible to keep clear of theory in any systematic presentation of fact, and while the necessity for such underlying conceptions may be masked so long as one is concerned only with reporting the results of individual experiments, the lack of guiding principles will appear whenever the attempt is made to bring together a group of particulars in a systematic review. Dr. Arnold's recapitulation of the discussion of attention, for example, suffers from the lack of a principle of division distinctly conceived and persistently adhered to. He begins this review by pointing out that "attention must be considered from two points of view," the sensory and the motor, a dualism which is expressed also in the terms "ideal" and physiological. The reader naturally assumes that this statement, with which the recapitulation begins, represents the last result of the writer's analysis, that the distinction is fundamental to the phenomena of attention. But Dr. Arnold goes on immediately to say that there are two aspects of attention, the subjective and the objective, of which the former includes both the sensory and the motor processes above mentioned. If this be so, it should be pointed out on behalf of the reader that the conditions of a good exposition surely require the more fundamental distinction to be presented first. That the latter distinction is basal appears from the following page, in which the subjective-objective is made the most general phase of the discussion.

The schema in question formulates the phenomena of attention in a way which is of permanent value, but as the grouping is not, in strictness, the order followed in the previous discussion, it can scarcely be called a recapitulation. One must drop the old subdivisions which he carried in mind throughout the reading, and substitute a new—though of course congruous—conception of relations. A question, too, may be raised concerning the propriety of the terms here employed. The aptness of the term "objective" to a summarization of the characteristics of clearness, distinctness and persistence may be granted, since these are, properly speaking, attributes of the object before consciousness, but a certain violence is done to a term already too loosely employed when accommodation and fixation, respiration and vaso-constriction, as well as fusion and free association, are made to fall within the field of the "subjective." Still more do the details of the schema reveal the need of logical formulation as well as of full citation of individual fact. The "subjective" aspect of attention, for example, is considered under the two heads, motor and sensory, but under the former appears also a subdivision entitled "motor," comprising the phenomena of innervation, diffusion and control. It is confusing, too, that under this term—which is not only popularly opposed to "sensory," but is also made its logical alternative in the present scheme—there should be made to fall the two subdivisions "sensory" and "motor" as minor terms. There is therefore the further contradiction that the term "sensory," which constitutes the basis of the second general division, should appear also as a special constituent of the first group of phenomena.

In each phase of the discussion Dr. Arnold has added to his description of the phenomena a consideration of their development in the individual mind. This is an important addition to the study which might profitably receive even more space than has been given to it. A series of illustrations is systematically appended to each chapter of the book. While these are in general well chosen, the reviewer finds some of them puzzling; but effective illustration is, after all, not only a matter of happy invention in the writer, but also one of idiosyncratic temperament in the reader, and the instances cited may nowhere present such obscurity to another mind.

ROBERT MACDOUGALL

SPECIAL ARTICLES

AN INTERMITTENT SPOUTING WELL

IN parts of central Florida bored wells are somewhat extensively used for drainage purposes The wells are drilled through the superficial material and as a rule enter the Vicksburg Limestone of Oligocene age, although other porous limestones may serve the same purpose Many of the wells terminate in cavities in the limestone, while others reach layers of shell or other porous material Surface water entering the wells is carried into the limestone formation. In some localities in the central part of the state these wells have been found very efficient in carrying off surface water and in draining small marsh areas for agricultural purposes

One of these drainage wells near Orlando, in Orange County, recently developed the unusual phenomenon of spouting The well was drilled in 1907 and is located near the edge of a small lake It is twelve inches in diameter and has a total depth of 260 feet, and is cased 60 feet The level of permanent underground water at this locality is 33 feet from the surface Trucking is carried on around the edge of the lake and the well is intended, by carrying off the surplus water, to prevent the lake from rising above a given level, since to do so would flood the farming land The well is similar in character to the other drainage wells of this locality and, as in the case of most of the other wells, terminates in a cavity in the limestone

The well was first seen by the writer October 4, 1910 At this time the water of the lake stood a few inches above the level of the top of the pipe, and the well was receiving water at much less than its full capacity At intervals of a few minutes the well would reverse itself and spout, throwing a column of water into the air The spouting comes on gradually First the well ceases to receive water and begins bubbling, the column of water follows, rising with considerable force to a height of twenty feet or more above the surface, the spout occurring with tolerable regularity at intervals of four minutes The manager of the farm states, however, that the interval between spouts varies from two to fifteen minutes, being probably influenced by varying conditions under which the water enters the well[1]

Although drilled three years ago and receiving water more or less continuously during that time the phenomenon of spouting developed for the first time on September 26, 1910, the first spouting having occurred about eight o'clock in the morning of that day The well continued spouting without interruption for a little more than a week and until shut off by the owner

Various fanciful theories have been advanced to account for the spouting, including supposed occurrence of gas and oil, and the supposed influence of recently formed sinks in the interior of the state The true explanation is evidently much more simple At this stage of the lake the well is receiving water at less than its full carrying capacity and as the water enters the vertical pipe it forms a suction, carrying a large amount of air into the well, which doubtless collects in a chamber or cavity along the side or at the bottom of the well As the well continues receiving water the air accumulates under pressure in this chamber until ultimately the pressure under which the air is confined is sufficient to overcome the weight of the overlying water plus the inertia of movement, and hence rushes out with considerable force, carrying the column of water with it The fact that the well when first drilled did not spout and afterwards began spouting doubtless indicates that the essential conditions were subsequently developed either by caving or by other changes in the underground conditions

When partly shut off so that only a limited amount of water enters the well the air taken into the well is able to return to the surface freely and under these conditions spouting ceases It is probable that if an elbow is placed on the well, allowing the water to enter laterally instead of vertically, the amount of air taken into the well will be so far reduced that the spouting will cease Likewise when the lake rises so that the water stands several

[1] A photographic illustration of the spouting well will be found in the Third Annual Report of the Florida Geological Survey, pl 9, 1910.

feet above the top of the pipe entering the well the spouting should cease, since the pipe will then be carrying water at its full capacity with little or no air under these conditions entering the well As a matter of fact following the heavy rains attending the storm of October 17 and 18, 1910, the lake rose several feet and the well upon being reopened received water without spouting A similar spouting well at Albany, Ga, was described some years ago by Professor S W McCallie[8]

E H SELLARDS

TALLAHASSEE, FLA

GRAPHITE IN VEIN QUARTZ[1]

THE writer has recently discovered a graphitic quartz in Troup County, Ga, which has some geological significance, since it is entirely unlikely that the graphite is directly of organic origin. The graphite occurs in massive vein quartz and, recognizing the already known occurrence of graphite in pegmatite and gneiss at other localities, affords additional evidence of the inorganic origin of graphite under peculiar geological conditions

The graphite occurs in small flakes and in irregular bunches, two or three millimeters in diameter or length, disseminated through massive, clear quartz In fact, in the specimens at hand, except for iron stains, quartz and graphite are the only components of the rock Under the microscope, minute black crystals were noted, but the black color disappeared upon ignition, leaving the crystal form intact, indicating only a covering of graphite over minute quartz crystals The graphite, roughly estimated, forms only two or three per cent of the quartz at present exposed.

The nearest rock exposed in the vicinity of the quartz vein is a peridotite and it is not improbable that the vein is cutting this rock The quartz, of course, could possibly be derived from pegmatite, but at the surface neither feldspar nor mica were found with it The vein is evidently of small dimensions

[8] SCIENCE, N S, XXIV, p 694, 1906.

[1] Published with the permission of the state geologist of Georgia

The nearest strata of certain sedimentary origin are the Pine Mountain quartzites a few miles to the southward.

Whether the quartz was deposited from an aqueous solution or is of aqueo-igneous origin, the carbon must have been held in some form in the rock solution and the graphite deposited contemporaneously with the quartz Its dissemination, not cavity filling, through compact, crystalline quartz is sufficient evidence that it is not directly of organic origin or derived from the metamorphism of carbonaceous matter Perhaps the most suggestive theory of the origin of the graphite under these conditions is that it was derived from carbon dioxide (CO_2), or a hydrocarbon vapor held in the siliceous solution The presence of carbon dioxide in crystals of quartz is well known Smoky quartz from Branchville, Conn, yielded gas, analyzed by A W Wright, which contained 98 33 per cent. of CO_2.

OTTO VEATCH

CONCERNING SEXUAL COLORATION

IN the linnet of California (*Carpodacus frontalis*), after the post-juvenal (first fall) molt, the sexes are conspicuously different in color The female is obscurely streaked beneath with hair-brown on a dull white ground, above more uniformly hair-brown The male is usually red in color, on the whole chin, throat, malar region and chest, on the frontal and lateral portions of crown, and on the rump, otherwise the male is like the female The linnet would thus appear to provide a good case of "sexual coloration."

After the post-juvenal molt, there is, in both sexes throughout the lifetime of the individual, but one molt annually, taking place in August. *There is no pre-nuptial molt.*

In a large series of male linnets, leaving out the occasional aberrant examples which are distinctly yellow or orange, striking variation is shown in the shade and intensity of the red. Arrangement of the component examples by date, from September to July, shows this variation to parallel uniformly the lapse of time beyond the annual molt in August. In

the fresh fall plumage the red is of a dull pinkish hue (burnt carmine), there is thereafter a progressive change, slow in autumn, rapid in spring, until the breeding season finds the amorous males, bubbling with song, and going through various courting antics, arrayed in brilliant poppy red.

A nuptial attire has been donned, in the male only, but there has been no replacement of feathers; nor has there been an influx of new pigment into the feather as a former most unsound theory presupposed

Microscopical examination of various feathers appropriately selected during the period of molt, when old and new feathers are to be found side by side, discloses the following facts: In the newly acquired, unworn plumage, the red pigment is restricted to the barbs of the contour portion of each feather, except for their terminal portions to a distance of one millimeter from their tips These barb ends, which thus together constitute a band terminating each feather, and *all the barbules,* are white In the extremely old, abraded (spring and autumn) feather these grayish white end portions of the barbs in the overlapping feathers, and all the barbules, have simply been broken off through attrition and lost, thus removing the grayish obscuration, and disclosing the bright red of the barbs, the tone of which has not in fact changed one whit.

Thus wear alone has accomplished the nuptial brightening of dress. A difference of structure is evident between the pigmented and unpigmented portions of the feather, the former being by far the most resistant, the latter being so adjusted in extent and texture as to become disintegrated and lost at the advent of the season of mating.

The production of color in the growing feather in August is thus clearly anticipatory; and we observe here manifestation of a most delicate structural complex, so balanced as to bring about through purely extrinsic, physical agencies, a conspicuous brightening of plumage at the season of reproduction, seven to nine months later.

The chief point to which I wish to fix attention is, that the brilliant hue of the nuptial dress is thus in reality acquired at the post-nuptial (or annual) molt, several weeks *after* the season of mating, instead of immediately preceding This fall molt period is generally considered (as by bird fanciers and poultry raisers) to be the season of the year when the vitality of the bird is at its lowest ebb. Moreover, the organs of reproduction are at this time much reduced in size, and certainly quiescent in function. It would seem, therefore, that the production of the brilliant nuptial plumage in the linnet (and similar sequence of processes and results is well known to occur in many other passerine birds[1]) is *not* directly associated with a period of excessive sexual vigor, as a current theory postulates.

THE OKLAHOMA ACADEMY OF SCIENCE

The academy held its second annual meeting at the State University at Norman, November 25–26. In spite of the fact that this was only its second annual meeting, about forty papers were read, among which were the following.

"The Human Tonsillar Band as a Protective Organ," Dr J D McLaren

"Study of Lipase," H I. Jones

"The Physical and Chemical Changes in the Burning of Clays," L C Snider

"The Road Material of Oklahoma," L C. Snider

"The Future Sources of Power in Oklahoma," C N Gould

"A Brief History of Oklahoma Geology," C. N. Gould

"Comparison of the Four Mountain Uplifts in Oklahoma," C. N Gould.

"The Oklahoma Redbeds," C. N Gould.

"The Ecology of the early Juvenile Life of the Unionidæ," F B Isely

"The Unionidæ of the Red River Drainage System," F B Isely.

"Notes of the Experimental Study of the Growth and Migration of Mussels," F. B Isely

[1] See, especially, Dwight, *Annals N. Y. Acad. Sci.*, Vol. XIII., 1900, pp. 73–360

"A Method of Treating Complex Sulphides and a few of the Difficulties in Putting it into Practise," D D Dunkin

"Glaciation in the Pikes Peak Quadrangle," C H Taylor

"The Igneous Rocks about Cold Springs, Oklahoma," C H Taylor

"The Ancestral Form of the Testudinata An Embryological Study," H H Lane

"The Stratigraphy of the Oil Region of Northeastern Oklahoma," D W Ohern

"The Present Stage of the Canadian River," D W Ohern

"The Study of American Government in the Public Schools," Clinton O Bunn

"Nationalism versus Internationalism," J H Sawtell

"The Glass Sands of Oklahoma," Frank Buttram

"Relation of Ionization to the Toxicity of Disinfectants Preliminary Report," Oscar Harder

"A Rapid Method of the Estimation of Salts in Butter Preliminary Report," G Y Williams

"A New Rapid Modification of the Iron-hæmatoxylin orange G Method for Nerve Sections," A M Alden

"The Application of Astronomy to Historical Research," Henry Meier

"The Grignard Reaction," H I Jones

"Building Stone Possibilities of Oklahoma," L L Hutchinson

"The Available Coal of Oklahoma," L L Hutchinson

"The Physical Characteristics of the Negro," Dr A C Hirschfield

"The Origin of the Concave Profile of Volcanoes," D W Ohern

"The Human Heart and Dangers that Threaten it," G T Howerton

"Post mortem Findings in a Case of Pityriasis rubra pilaris," C D Blatchley

The academy appointed a committee, of which Dr C N Gould is chairman, to consider the advisability of securing state aid in publishing the proceedings of the academy Another committee was appointed to institute a biological survey of the state Of this committee Professor H H Lane is chairman The academy is using all the influence that can be possibly brought to bear upon the people of the state to push forward the study of the various animal and plant forms before the influence of man disturbs natural conditions

The next annual meeting of the academy will be held at the Central State Normal at Edmond, November 26–27, 1911

Assistant Secretary

THE ASSOCIATION OF TEACHERS OF MATHEMATICS IN THE MIDDLE STATES AND MARYLAND

The fifteenth meeting of the association was held at the University of Pennsylvania, Philadelphia, on November 26, 1910 The program for the morning session was

Address of welcome, Edgar F Smith, vice-provost, University of Pennsylvania

Miscellaneous business

"Is the Average Secondary-school Pupil able to acquire a Thorough Knowledge of all the Mathematics ordinarily given in these Schools?" Isaac J Schwatt, University of Pennsylvania Discussion led by Rev James J Dean, Villanova College, Edward D Fitch, the DeLancey School, Philadelphia, and E B Ziegler, Conshohocken, Pa

Election of officers

Following the morning session the association was entertained at luncheon by the university

The program for the afternoon session was·

"Training for Efficiency in Elementary Mathematics," Ernest H Kock, Jr, Pratt Institute, Brooklyn

Report of the Committee on Mathematics in Continuation Schools, William E Breckenridge, chairman, Stuyvesant High School, New York City

Report of the Committee on Algebra Syllabus, Gustave Le Gras, chairman, College of the City of New York

The officers for 1910–11 are· *President*, William Henry Metzler, Syracuse University, Syracuse, N Y, *Vice-president*, Philip R Dean, Curtis High School, Staten Island, N Y; *Secretary*, Howard F Hart, Montclair High School, Montclair, N J, *Treasurer*, Mrs Clara H Morris, High School for Girls, Philadelphia, Pa, *Council Members*, Paul N Peck, George Washington University, Washington, D. THE BROADER ASPECTS OF RESEARCH IN TERRESTRIAL MAGNETISM[1]

IT has become the custom—fortunately or unfortunately as the case may be—that the retiring presiding officers talk on a particular subject, announced some time ahead, instead of being permitted to indulge in merely general reviews, as is the case in some organizations Before I had a chance to think definitely on the matter, request was received from the permanent secretary four months ago that the title be furnished him at the earliest possible moment

My original desire was to have the opportunity of talking to you on some more general subject than the one I have finally chosen The topic, magnetism in general—a review of our fundamental ideas, the status of researches on the question "What is a Magnet"—appealed to me strongly In connection with my researches in terrestrial magnetism, I have naturally been obliged to look occasionally out beyond and raise questions on the general problem of magnetism. When not only the permanent secretary, but the secretary of this section and the present chairman, began to make inquiries as to my subject, I had to settle upon something And when I turned to your chairman for assistance in coming to a decision, and submitted to him several topics, *e g*, "The General Problem of Magnetism," "The Physical Bearing of Problems of Terrestrial Magnetism," etc, he indicated his preference for one relating

[1] Address as retiring vice-president and chairman of Section B (Physics), American Association for the Advancement of Science, given at Minneapolis, Minn, December 29, 1910

to terrestrial magnetism, for he said, "A man usually talks best on the subject he knows best" Note the diplomatic and graceful manner in which he intimated to me that I might possibly know a little more as to the earth's magnetism than of magnetism in general However, since magnetism is one of his own particular fields of research, may we not hope that he will decide to talk to us about this broad subject himself when he reaches the retiring age?

In fact, I am quite ready to confess ignorance of the most absolute kind on the whole subject of magnetism, terrestrial as well as general And I am all the more willing to do so because I find myself in excellent company Was it not von Helmholtz who characterized "magnetism as the most puzzling of natural forces"? Did not Rowland say that next to gravity, the greatest problem is that of terrestrial magnetism? Was it Lorentz who said that our ignorance in magnetism is the disgrace of modern physics, or words to that effect?

On the whole, it perhaps does seem best that one should talk, as far as he can, on an occasion like this, concerning a subject from his own directly acquired knowledge As a retiring president of the British Association some years ago aptly said, when apologizing for confining himself chiefly to his own immediate subjects instead of attempting a complete general survey of the progress of science "Partial views are better than inexact ones, and provision is made for their completion in the annual change of your officer"

I must take it for granted that I owed the honor of my election as vice-president and chairman of this flourishing section, two years ago, to the fact that it has been my privilege to contribute something towards the stock of our knowledge of the earth's magnetism I may therefore assume that you want me in the first instance to "reveal myself in my own subject" I will then only ask one favor of you in return, that you allow me to omit more or less wearisome details and deal to-day only with some of the broader aspects of terrestrial magnetic research

Professor Arthur Schuster, during his visit to Washington last September, one day remarked jokingly to the speaker, "I am not quite sure whether it has really been best to have a special journal on terrestrial magnetism for gathering in the chief papers For when no such organ existed physicists *saw*, at least occasionally, an article on the subject in their journals, even if they did not read it" The presumption evidently was that physicists nowadays have less opportunity for imbibing knowledge on terrestrial magnetism and kindred subjects

So then, if I, a *terrestrial* magnetician, may be pardoned for knowing but little of magnetism, or, for that matter, of physics in general, possibly the *pure* magnetician or the pure physicist would likewise in turn have a valid right to ignorance in terrestrial magnetism and cosmical physics, were it not for the contradictory fact that he is often found to be the author of our encyclopædia articles on these very topics His wisdom in these particular fields appears to be gained in that wholesome and unwearisome manner employed by Herbert Spencer, who "never began by attempting to learn what had already been said." "All my life," said he, "I have been a thinker and not a reader, being able to say with Hobbes that 'if I had read as much as other men, I should know as little as they.'"

We are to spend a few moments together to-day in looking at some of the broader aspects of physical research in a field that, with justice, many of you may look upon

as an exceedingly special and restricted one and perhaps even question its right to be classed among the physical sciences And yet this subject of the "earth's magnetism," which may consider itself fortunate if a brief section is devoted to it in the average text-book of physics, is itself so broad and so extensive that I know of no single investigator who could to-day be regarded as equally eminent in all its various branches and sub-branches To be a master in terrestrial magnetic research requires the most intimate knowledge of several of the so-called fundamental sciences, especially of mathematics, physics and geology, with some knowledge of astronomy, meteorology, chemistry and geography besides "The field of investigation," says Maxwell, "into which we are introduced by the study of terrestrial magnetism, is as profound as it is extensive"

MAGNETIC DISTURBANCES

Instead of beginning with the phenomena usually chosen to illustrate the earth's magnetism, let us begin with one of the irregular, more or less spasmodic manifestations—one of the so-called "abnormal features"—the earth's "magnetic storms" as they were termed by Humboldt Because of the troublesome nature of magnetic disturbances, when one is dealing with a phenomenon like the diurnal variation, for example, various magneticians for nearly three quarters of a century have been seeking some logical method of deciding just at what point a disturbance begins —in brief, how large must be the fluctuation in a magnetic element to be classed and eliminated as a "disturbance" Various rules have been set up, but none has found general acceptance

There was a time when it was thought that, by mere inspection of the photographic record of the variations of a magnetic element during the day, it was possible to say whether that particular day was disturbed or not, and so arose in Great Britain, for example, what are called the "astronomer royal's five quiet days during the month" Through Airy's initiative, the first English magnetic observatory was established at the Greenwich Observatory during that period of intense magnetic activity which prevailed in the first half of the last century—during the days of Humboldt and Gauss The honor of deciding on the five quietest days in any particular month from which the "normal" diurnal variation may be deduced, has therefore been accorded to the head of the Greenwich Observatory, these days are selected by him, or more likely by his magnetic assistant, from a mere inspection of the photo-magnetograms However, it has been found that these supposedly quiet days may themselves be subject to a more or less constant disturbance which, prevailing throughout the day, serves to elevate or depress the entire curve and hence does not reveal itself in superposed serrations or "eruptions" Or the disturbances may follow somewhat the same course as the diurnal variation itself, and hence again not be revealed by mere inspection, but serve mainly to increase or decrease the diurnal range

Van Bemmelen and Chree have also found that these supposedly quiet days are subject to a non-cyclic effect similar to that shown by other days I recall that during my first magnetic survey—that of Maryland, 1896–99—there were months when a searching examination of the photographic records of the magnetic observatories showed that there was hardly a day out of a whole month without some kind of irregularity.

It is then evident that a phenomenon which occurs so frequently and which in

fact appears ever to be present in some degree, at least, in the prevailing magnetic condition of the earth, is hardly to be treated as an outcast or as an "abnormal" feature I very much question whether it will ever be possible to set up any rules which will separate scientifically the supposedly abnormal from the supposedly normal fluctuations of the earth's magnetism I am rather inclined to believe that as progress is made there will be fewer and fewer attempts in this direction On the contrary, *instead of eliminating a disturbance because it will not fit in with a particular mold or pattern, we shall learn that knowledge is mostly to be advanced by retaining it*

In order to have something definite with which to deal I am going to ask you to confine your attention to-day chiefly to the abruptly beginning magnetic disturbances, bearing in mind, however, that not all magnetic storms begin thus The first interesting question which arises regarding these sudden storms is whether, if referred to universal time—say, Greenwich mean time —they begin, within the limits of measurement, at the very same instant over the entire globe, or at least over a great portion of it Up to the beginning of this year it was, indeed, generally believed that there was no measurable interval between the times of beginning of sudden disturbances even for very distant stations The opinion was that the time differences which were revealed were only apparent ones, not real—that, if there were no errors of observation, they would vanish So the belief arose that it might be possible to find the longitude between two distant stations by determining with the utmost accuracy the local mean times of identical perturbations, for, be it remembered, even the very smallest of these find their counterparts frequently at very remote stations.

A magnetic effect propagated with the velocity of electromagnetic waves would require but one eighth of a second to pass completely around the earth, if with the speed of a cathode ray, the circuit time would be on the order of a half or three fourths of a second If then magnetic disturbances were propagated over the earth with such velocities, our present instrumental means would not suffice to detect any time differences between stations, though on opposite sides of the earth If, however, differences of whole minutes are found instead of only fractions of a second, it will at once be seen that a most valuable clue has been obtained towards disclosing the nature and origin of our magnetic storms It is my belief, furthermore, that *a long step forward will have been taken towards the solution of the origin of the earth's magnetism when once we have found out what causes it to vary*—what it is that can derange the magnetization of our entire planet to the extent of ten to twenty per cent in the brief interval of a quarter of an hour, as actually occurred during the magnetic storm of September 25, 1909, the most notable of which we have any record Referring to changes in the earth's magnetism, insignificant alongside of those just mentioned, viz, the secular changes, which only reach a comparable amount when integrated over a period of several centuries, Maxwell says: "When we consider that the intensity of the magnetization of the great globe of the earth is quite comparable with that which we produce with much difficulty in our steel magnets, these immense changes in so large a body force us to conclude that we are not yet acquainted with one of the most powerful agents in nature "

I would now like to call your attention to some interesting facts found with regard to 38 of these sudden disturbances which

occurred during the years 1882–1909 No 1 of these is the unique magnetic disturbance of May 8, 1902, which, as far as can be ascertained, occurred simultaneously with the destructive eruption of Mont Pelé On account of this interesting coincidence the records of twenty-five observatories in different parts of the world were collected and studied in my office When the various scalings of the time of beginning of the disturbance were put together, they appeared to increase to the east, the effect apparently having been recorded first in Europe, next in Asia and last in America The speed of progression was such that a continuous circuit of the earth around a great circle would require nearly 4 minutes, or in other words, the velocity was on the order of 100 miles per second or only about one two-thousandth that of light

No 2—the disturbance of January 26, 1903—was one investigated by the eminent physicist-magnetician Birkeland, the author of the cathode ray theory of magnetic disturbances. For this again an easterly progression, on the same order as for No 1, was found

Next, Nos 3–19 are 17 storms between 1882–89 which were investigated by William Ellis, who was for a half-century in charge of the magnetic work at Greenwich.

The nineteen cases thus far mentioned showed a remarkable consistency in the direction in which the times increased, viz, to the eastward, only one sixth showing the reverse direction

In order to test this result further with the aid of the best data immediately available, Mr. R. L Faris, Inspector of Magnetic Work of the United States Coast and Geodetic Survey, undertook, at my request, a special examination of fifteen sudden storms between 1906 and 1909. He had to restrict himself for the time being to the five magnetic observatories belonging to the United States, viz, Cheltenham (Maryland), Porto Rico, Baldwin (Kansas), Sitka and Honolulu, which extend over about one quadrant of the earth Mr Faris scaled the times of beginning with every possible care, he estimated that the error of measurement was about one half minute and certainly not over one minute Yet the individual observatories differed by quantities ranging from 1 1 to 6 7 minutes! Here again, for 10 out of 15 cases, the direction of progression, over the limited portion of the earth embraced, was eastward, and for only one third was it westward.

The next four cases are some tiny preliminary disturbances preceding larger ones, investigated by the director of the Zi-ka-wei Magnetic Observatory, Father J de Moidrey, and by Mr Faris, for two of these the direction of progression was east, and for two, west

Summarizing—for 28 out of the 38 cases the times of beginning increased eastward and for but 10, or about one fourth, the increase was in the reverse direction The following conclusion was accordingly drawn

Magnetic storms do not begin at precisely the same instant all over the earth. The abruptly beginning ones, in which the effects are in general small, appear to progress over the earth more often eastward though also at times westward, at a speed of about 100 to 200 kilometers per second, so that if a complete circuit of the earth were made it would require, on the average, between 7 and 3 minutes.

DIRECTION OF MOTION OF MAGNETIC DISTURBANCES

If it is a fact that magnetic disturbances are propagated more decidedly in one direction than another and that they dif-

fer, in this respect, from seismic disturbances which proceed in all directions from the center of disturbance, then a harmonic analysis of the disturbance effects should furnish further evidence. A definite electric or magnetic system must be accompanied by equally definite effects on our suspended magnetic needles. Knowing the latter, we ought, in turn, to be able to determine the general character, at least, of the producing system.

The beginning of the disturbance of May 8, 1902, may be taken as typical of the general type of perturbation thus far considered, viz., an increase in the horizontal intensity over the whole, or at least the greater part, of the earth, and a decrease in the vertical intensity in the northern magnetic hemisphere, and an increase in the southern. Applying a mathematical analysis, it is found that the system of forces which could produce the observed disturbance was a two-fold one—the first, the stronger, consisted of a set of electric currents in the upper regions, circulating eastward around the earth, if negative currents, and the reverse, if positive ones; the second, a weaker system, contained within the earth and possessing the characteristics not of an induced electric system, but of directly induced magnetism of the same sign as that of the earth's own field.

Please note that according to this analysis the disturbance system is chiefly an overhead set of currents proceeding, if negative ones, in an eastward direction around the earth—but this, in fact, is the direction in which the recorded times of beginning of the disturbance were found, in general, to progress. One method of investigation thus independently supports the other.

How may we suppose that negative electric currents are brought about in the regions above us which could thus affect our magnetic needles? If the progression in the times of beginning of the effect may be interpreted as meaning that, whatever the cause, it is moving with a velocity measured by the differences in the times at distant points on the earth, then the resulting velocities are on the order of about one two-thousandth that of electromagnetic waves, or about one four-hundredth that of cathode rays. The question immediately arises—May not the required overhead negative electric currents be brought about by rapidly moving electric charges, whose accompanying magnetic perturbations are but an exhibition of the Rowland effect on a scale far transcending any laboratory experiment within the power of man? We may be dealing with ionic charges set in motion, as the result of a releasing action from some quarter, by sources of energy already existent in the regions above us, whence currents arise—

> "Of power to wheedle
> From its loved north the subtle needle,"

as Maxwell said with regard to the convection currents, which "that doughty Knight, Rowland of Troy, did obtain."

Now before indulging in a bit of scientific imagination, let me caution you to distinguish carefully between what is fact and what is hypothesis. The results communicated respecting the differences and progression in the times at which sudden perturbations occur, as well as those derived from the mathematical analysis of the recorded effects, are independent of theory. You may not agree with me in any hypothesis which I may attempt to establish as to the cause of magnetic disturbances and the *modus operandi*, but please remember that the facts remain, however difficult may be the problems which they present.

HYPOTHESIS OF IONIC CURRENTS

According to the measurements of Rutherford and Zeleny, the average total ionic velocity for dry air at the earth's surface and an electromotive force of one volt per centimeter, is 3.2 cm./sec. At this rate it would take forty years to encircle the earth. Putting together all the facts of laboratory experiments at present available to me, including the work carried out at the laboratory[3] here by Zeleny and Kovarik, a provisional calculation appears to show that, for the atmospheric pressure prevailing at about the height of 75 kilometers, the ionic velocity would be of the order required for a circuit of the earth in about four minutes—hence, of the order found above to correspond with progression of the observed times of beginning of a sudden magnetic perturbation.

A mathematical analysis of the magnetic observations made at various points on the earth's surface has revealed the existence of a definite system of atmospheric electric currents whose magnetic effects are of sufficient magnitude to require their being taken into account when determining the so-called magnetic constants of the earth. Now if the atmosphere is made more conducting at any point, as the result, for example, of the ionizing effect from solar radiations, an extra current will be started and set in motion by the electromotive force existing at that point. The direction finally followed by the extra current will, however, not depend alone upon the prevalent electromotive force, but also upon the deflecting effect of the earth's magnetic field and of the earth's rotation on the electric carriers, and doubtless upon a variety of other conditions.

If a negative ion is set in motion at a given altitude in an eastward direction, the deflecting effect of the earth's magnetic field will be to bring it down closer and closer to the earth. But the ionic velocity decreases with decrease of altitude, hence the magnetic effect produced by the moving charge on a needle at the earth's surface will begin later and later, as the charge travels eastward. If, on the other hand, the negative ion starts westward around our planet, then the deflecting effect of the earth's magnetic field would be to make the charge move higher and higher and, hence, faster and faster. We might thus possibly have the following state of things. Due to some cause, electric charges are set in motion in every direction from a certain point overhead. Those with an easterly component of motion have their velocities checked in the manner just described, whereas those with a westerly component are made to move faster, so that for two stations, one east and one west, the magnetic effect is recorded later at the east station. This deduction you will observe would correspond with that actually found for the vast majority of the 38 disturbances above treated. In brief, the deflecting effect of our own magnetic field would be favorable towards the maintenance of easterly progressing negative ions, since by bringing them closer to the earth their effect is increased, and unfavorable for the westerly ones since they are made to move farther and farther away from the earth. Whether it is due to this fact that a sudden disturbance progresses more often to the east than to the west is an interesting query.

[3] The Physical Laboratory of the University of Minnesota.

THE PECULIAR MAGNETIC DISTURBANCES OF DECEMBER 29–31, 1908

I want to make you acquainted next with another set of most instructive magnetic disturbances which differs from the kind previously considered in several important

respects The effect of the previous type of disturbance was to superpose, on the earth's existing magnetic field, a subordinate magnetic system possessing essentially the same characteristics as the primary field, differing from it only in degree—in brief it *increased* momentarily the earth's magnetization, and hence might be termed a "positive magnetic perturbation" It was also a world field—its effects were recorded all over the earth

But now we are to have examples of a "negative magnetic perturbation," whose effect is to superpose a magnetic field opposite to that of the earth, in short, diminish the earth's prevalent magnetization, and whose area of action is a comparatively restricted one These perturbations were not felt over the whole earth within a few minutes of the same absolute time, instead the intervals between the recurrences in different parts of the earth were to be measured by hours and even a day

Attention was first called to these peculiar magnetic disturbances by D L Hazard, of the United States Coast and Geodetic Survey, and recently R L Faris, of the same organization, has collected information regarding them from a large number of observatories over the globe These disturbances did not extend much over one half hour and occurred on a practically undisturbed day The maximum deflection in the horizontal component of the earth's magnetic intensity amounted to about one five-hundredth part The complete data will be found given by Mr Faris in the March, 1911, issue of *Terrestrial Magnetism and Atmospheric Electricity* I am indebted to him for the privilege of making use of his data in advance of publication

Four times out of eight cases the region over which the disturbance prevailed was the American continent and the Pacific Ocean as far as Honolulu, in one case the region was limited to the Atlantic Ocean and the American continent, twice it occured in eastern Asia and but once in Europe Hence, had we been obliged to rely solely upon the magnetic records from the region of the earth, Europe, where the majority of magnetic observatories exist (about 20), we should have had to report but one magnetic disturbance between December 29 and 31, 1908, instead of actually eight No fact known to me illustrates more convincingly than this the folly of increasing greatly the number of magnetic institutions in the same region of the globe It also proves that, when dealing with general terrestrial magnetic phenomena, no such weight can be attached to the combined testimony of the European observatories as has heretofore been the custom To give weight, as is frequently done, according to the *number* of existing magnetic institutions in any one region leads to totally erroneous results We are reminded of the wise words of Joseph Henry which, though uttered in a different connection, apply with special force here, viz, "*Votes in science should not be counted, but weighed*"

Now why is it that these particular magnetic perturbations were confined each time to but a portion of the globe? The intervals in time between the successive occurrences range from $1^h 5^m$ to $24^h 21^m$, whereas the apparent velocities shown over the area covered at any particular appearance of the disturbance is on the order of the quantities as previously found for the first type of disturbance considered The question immediately arises, therefore, as to whether we are dealing here with *two* velocities Have we, for example, a vortex consisting of very rapidly moving electrical charges, an earth-spot, as it were, the vortex as a whole, however, moving

comparatively slowly over the earth? Or, are we to suppose that at each recurrence the disturbance was formed anew? No matter what view we adopt, it is evident that we are about to find out another important fact.

Determining the local mean time of the extreme stations at which the disturbance was recorded whenever it occurred, it is immediately seen that *only the observatories in the daylight zone were affected* At those observatories where the local time was somewhere between 4 P.M. and 6 A.M., no effect was obtained Hence, the conclusion is inevitable that *solar radiations of some kind must have played an important part in the production of these disturbances* There were at the time on the sun's visible disk some peculiarly eruptive spots which may have to be held responsible for the peculiar magnetic disturbances

A mathematical analysis of this type of magnetic perturbation is at present under way, but it has already become sufficiently evident that we are dealing here with a much more complex system than in our first type.

GENERAL DEDUCTIONS RESPECTING MAGNETIC DISTURBANCES

From the two types of disturbances considered it has been found that not only may our most sudden magnetic disturbances begin at measurably different times for various points on the earth's surface, but also that magnetic perturbations may even be confined to but a very limited portion of the globe

The possibility of a regional magnetic disturbance was foretold with the aid of a law which I found to hold regarding magnetic changes in general:

"*Alterations in the earth's magnetic condition, whatever their nature or origin may be, appear to be distributed over the globe according to a law profoundly dependent upon that governing the distribution of the earth's own primary magnetic forces*"

The prediction made on the basis of this law last spring, before the facts had become known respecting the disturbances mentioned, was as follows:

> I confidently expect, as soon as a complete analysis has been made of magnetic disturbances covering the greater portion of the earth, it will be found, that the disturbance field, in general, presents all the characteristics of the terrestrial, primary one, the disturbances will themselves reveal effects from terrestrial, continental, regional and even local causes (earth currents, for example, whose path and intensity depend upon local character of soil, etc)

Were this the place, I should like the privilege of setting before you the full import of this law How, for example, we find characteristics in the magnetic fields composing the so-called permanent magnetization of the earth analogous to those which represent the systems producing the time variations Suffice it to say that, if we were to establish a mathematical expression for the respective systems involved, the same terms would appear in the space variations as in those of the time. We might tersely put it thus "*In terrestrial magnetism space and time are often relatively interchangeable*"

Before leaving the subject of magnetic disturbances let me point out to you two or three additional interesting facts which may serve to guide us in our study of causes.

It is the usual custom to exhibit the dependency of the fluctuations in the earth's magnetic condition during a sunspot cycle by means of changes in certain particular magnetic elements, as for example, the change in the amplitude of the diurnal variation during the sunspot cycle, this amplitude increasing with increased solar

activity If, however, we make use of a more direct physical quantity, viz, the earth's magnetic moment, or let us say intensity of magnetization per unit volume, then we find that, *in general, during a sun-spot cycle the earth's magnetization decreases with increased solar activity* In brief, on the average, the effect of magnetic perturbations is to superpose on the earth's magnetic field a magnetization opposite to that of its own, and hence the effect is one of demagnetization The quantity involved is on the order of that found some years ago when I raised the question as to whether the earth is gaining or losing magnetism

This question was attacked in two different ways, first, use was made of the existing magnetic charts between 1840 and 1885, secondly, freshly accumulated data between the years 1890 and 1900 were utilized Both investigations led to the same result, viz, that *the earth's magnetic moment is at present being diminished by about one twenty-four hundredth part annually* Now, if the terrestrial magnetician were permitted to make the same apparently violent extrapolation as is indulged in by the radio-physicist, he would find that, at the present rate of decrease, the earth's magnetic moment will have dwindled to one half of its present value in about 1,660 years from now Note that this period is practically the same as that of radium decay—probably a mere coincidence!

We may make use of magnetic perturbations in another way, mainly, to get some idea of the *earth's magnetic permeability* I have already pointed out above that when analyzing the effects of the magnetic disturbance of May 8, 1902, it was found that there were two systems involved, one an external one composed of overhead electric currents, and the other, an internal one having the characteristics of directly induced magnetism If we suppose that the second system is the result of the first, then the ratio of the potentials of the two systems will give us the differential change in the earth's magnetic permeability Various calculations of this kind are under way

One of the most important bearings of the facts above set forth regarding magnetic disturbances pertains to the slow, progressive changes to which the earth's magnetization is subject—secular changes It has already been hinted above that these *secular changes can not be explained simply by a change in the direction of the axis of magnetization, but likewise imply changes in the intensity of magnetization* Respecting the latter, our result was that apparently the residual effect of a magnetic disturbance is a diminution of the intensity of magnetization, which may last for some period after the cessation of the disturbance, two months, for example, as occurred with respect to the notable magnetic storm of September 25, 1909 Whether the earth ever recovers completely from a magnetic disturbance is questionable

Now, *as to the effect of magnetic disturbances on the axis of magnetization,* let me merely point out that if magnetic disturbances do actually in general progress over the earth more often in one direction than in the other, the mechanical effect is to be reckoned with If the progression is generally eastward, as appears to be the case, then the mechanical effect of the overhead currents will be to increase the velocity of the earth's rotation or, failing to do that, which is more probable, the effect will be to cause a displacement of the earth's magnetic axis eastward. We thus have disclosed to us one of the several systems causing the secular variation of the earth's magnetism which was pointed out in 1904

as the result of my analysis of the systems causing the secular variation

The principal system, however, involved in the production of the secular variation is still to be revealed, and a promising line of inquiry, at present in progress, is the concomitant study of the laws followed by the secular variation and the lunar diurnal variation of the earth's magnetism, I have found that both follow remarkably similar laws in their distribution over the earth It might also be mentioned here that owing to the non-commensurability in the periods of the solar-diurnal and the lunar-diurnal variations, there is an outstanding daily residual of the right magnitude for the production of the secular variation

Sufficient has been given to show how important and fruitful is the study of the "abnormal" features of the earth's magnetism It seems probable that we shall learn more from a close investigation of magnetic disturbances—of the irregular phenomena—than of the normal and regular features In any event we find that the "abnormal" is such an intimate part of the supposedly "normal" that it seems unwise really to make a separation We fully endorse the view of Schuster when he says

> Outbreaks of magnetic disturbances, affecting sometimes the whole of the earth simultaneously, may be explained by the sudden local changes of conductivity which may extend through restricted or extensive portions of the atmosphere I have shown in another place that the energy involved in a great magnetic storm is so considerable that we can only think of the earth's rotational energy as the source from which it ultimately is drawn

According to the views above set forth, the various manifestations of solar activity, sunspots, protuberances, etc, are not the direct but the indirect cause of the earth's magnetic storms Their effect appears to be more in the nature of a releasing or "trigger" action, setting in operation electric forces already in existence in the upper regions of the atmosphere, terrestrial sources, in reality, however, supply the energy required for the magnetic storm

THE EARTH'S PERMANENT MAGNETIC FIELD

Our studies began with magnetic disturbances, and we soon found that we were dealing with systems of forces remarkably similar to those composing the earth's permanent magnetic field Given an existing electrical field in the upper regions, it follows at once, from our knowledge of the necessarily varying conductivity of the atmosphere resulting from solar radiations of various kinds, that this field must be an exceedingly variable one First, it must be subject to a daily variation of an average normal kind corresponding to the average normal solar radiation, and superposed on this more or less spasmodic fluctuations, which represent the variability in the supply of the essentials in the solar radiations for producing the observed magnetic effects

In this connection let me point out an interesting bit of evidence furnished during the time of the total solar eclipse which occurred in the United States in May, 1900 As the result of the special magnetic observations, made chiefly by the observers of the United States Coast and Geodetic Survey, a small magnetic perturbation revealed itself at each station along the belt from Georgia to Maryland This perturbation did not begin according to absolute time nor according to local mean time, but bore a distinct relation to the time of passage of the shadow cone It was thus shown that by the interposition of the moon between the sun and the earth, certain radiations were cut off as the result of which a magnetic fluctuation was produced I recall that the late Professor Newcomb appeared rather skeptical as to

the possibility of a magnetic fluctuation due to such a cause until one day he put this query to me "If a magnetic effect is produced when such a small body as the moon comes between the sun and the earth, why do we not have an effect every day owing to solar radiation being cut off from one half the earth by the other?" Professor Newcomb had momentarily forgotten that we do have a daily effect of the very kind he had in mind, viz., the diurnal variation, and when I pointed this out to him he appeared convinced as to the possibility of a magnetic effect likewise during a total solar eclipse I have shown that the magnetic effect during a total solar eclipse is precisely similar to that of the diurnal variation, differing from it only in degree and that the amplitudes of the respective oscillations are in direct proportion to the areas of the interposing discs

Please recall also that in the second type of disturbance above treated, viz., those of December 29–31, 1908, we had further evidence of perturbations occurring only in the daylight zone, the inhabitants on the other side of the earth did not experience the perturbations

If then so much can be explained or, let us say, suggested, on the supposition of an existing primary electric field in the region above us, then it behooves us to do our utmost to find out all we can as soon as possible regarding this field And here is where the great value of the extensive magnetic operations of the Carnegie Institution of Washington will be demonstrated, for the precise characteristics of that outside electric field can not be accurately determined until the completion of a general magnetic survey of the globe When that has been accomplished, which we hope will be the case within the next five or ten years, then the constants, or rather the determining coefficients, can be derived for the various constituent portions of the earth's total magnetic field.

Before closing this section let me call to mind a fact that is frequently overlooked, that *our only cognizance of the earth's magnetic field is through its external lines of force* Cut these out, and we would conclude, in accordance with our usual test, that the earth was not magnetized But we might have closed magnetic systems within the earth similar to that of a magnetized ring Such a ring, however strongly it may be magnetized, has no outside magnetic effect and if we had no previous knowledge of its internal magnetization, we would conclude from our usual experiments that it is non-magnetic I know of no method of disclosing such magnetizations as that of the ring without producing some mechanical change in the ring itself. Accordingly, our knowledge of the earth's primary magnetism would be confined wholly to external effects, were it not for the fortunate fact of the variations continually caused in the earth's magnetism by outside forces You will therefore see the point to my statement that, in my belief, *it is useless to attempt an explanation of the origin of the earth's magnetism until we have found out what causes it to vary.* Perhaps even then it may turn out that we shall have to be content with simply raising the question already put by Schuster whether "every rotating mass may not be a magnet."

In this connection let me record here an interesting fact which I found some years ago If we determine the earth's magnetic axis and intensity of magnetization per unit volume separately for various parallels of latitude, then there is a distinct connection shown in the values of the constants involved with the speed of rotation of a particle on the parallel concerned.

A BROAD VIEW

I began my address by setting before you some of the results of research in a field which I am ready to acknowledge appears, as I have already said, a very restricted and special one But as we progress we are continually forced to raise questions which go far beyond our specialty and touch at the very heart of matters in which we all take a common and lively interest

The all-comprehensiveness of terrestrial magnetic phenomena makes us more than ever aware of the necessity of taking broad views and keeping our minds ever open and free so that we may receive and weigh the facts observed with the proper care and in the proper scientific spirit

The terrestrial magnetician is continually having forced upon him the fact that the "axis of the universe does not stick out of his own back yard" He can not follow the example of his more fortunate brother, the geodesist, who, from careful measurements made over but a very limited portion of the earth can determine its figure with wonderful precision, the best possible demonstration of which we shall have today from the address of the retiring chairman of Section D To the geodesist a mass of lead is the same as an equal mass of magnetic iron ore, not so, however, to the magnetician Were he to attempt the determination of the position of the earth's magnetic axis and of the earth's magnetic moment from a series of extensive magnetic observations in the United States, he would obtain results totally different from those similarly derived for an area of equal size in some other part of the globe So likewise, as we have found with respect to the earth's magnetic disturbances, five well distributed magnetic observatories can accomplish more, viewed from a general, terrestrial standpoint, than twenty of the best equipped magnetic observatories concentrated in but a limited portion of the earth, however civilized that portion may be

Thus the student of magnetism has difficulties not encountered in geodesy, and he would appear to suffer under great disadvantages. Perhaps, however, the disadvantages under which he labors as regards one object may become a source of advantage in a totally different one, by the very fact that to the magnetician a lump of iron is different from a similar mass of lead he is enabled to draw certain conclusions with regard to the materials forming the earth, denied to the geodesist One of our foremost geologists has predicted that our knowledge of the internal constitution of the earth is to be advanced primarily through terrestrial magnetism and seismology

Beginning with Gauss and up to within comparatively a few years ago, it was believed that it would be possible to establish a mathematical expression having a limited number of coefficients which would represent the magnetic observations made over the earth's surface, if not entirely within an error of observation, certainly within an error of approximately the same order However, as carefully conducted magnetic surveys become more extensive, it is becoming more and more evident that it is useless, for practical purposes, to establish such mathematical formulas Were we, for example, to have magnetic data all around the globe at intervals of five degrees in latitude and longitude, hence at 72 points on a parallel, it would be possible to set up a formula which should represent absolutely the values at the points given, but even for this case the expression would involve so many unknowns as to make the computation practically prohibitive. And after all this labor had been accomplished, it would not be possible to obtain the mag-

netic elements between the five-degree points and within the accuracy attainable even by ocean magnetic work. In fact the outstanding residuals would be on the order of 10 to 100 times the error of observation. This inability to represent the earth's magnetic condition by means of a closed mathematical formula having a definite physical interpretation might again be looked upon as a disadvantage. I, however, am inclined to look upon it as an advantage, for we have thereby a definite proof of the fact that magnetic observations are sufficiently delicate to disclose all of the heterogeneities and irregularities in the constitution of our earth. Had we time we might profitably spend a few minutes in looking at the testimony which may be furnished the geologist in this respect by the magnetic needle.

In conclusion permit me to refer to an incident which occurred at the meeting of the British Association held at Bristol in 1837. Sir William Hamilton, attending the session of the Chemical section and getting into a quarrel with his chemical brethren, remarked: "The nearer all the sciences approach Section A (mathematics and physics), the nearer they would be to perfection." I would make but one slight alteration in this assertion, namely, that the nearer we all approach to mathematics and *cosmical* physics, the nearer we should be to perfection.

L. A. BAUER

THE CARNEGIE INSTITUTION
OF WASHINGTON

CHARLES OTIS WHITMAN

PROFESSOR CHARLES OTIS WHITMAN, head of the department of zoology of the University of Chicago, died of pneumonia after a brief illness on December 6, 1910. He was born in Woodstock, Maine, December 14, 1842. He received the degree of A.B. from Bowdoin College in 1868, and A.M. in 1871. From 1869 to 1872 he was principal of Westford Academy and in 1872 was teacher in the English High School of Boston. A few years later he was studying zoology with Leuckart in the University of Leipzig and received the degree of doctor of philosophy from this university in 1878. From 1880-81 he was professor of zoology in the University of Tokio, and in 1882 we find him studying at the Zoological Station of Naples. From 1883-85 he was assistant in the Zoological Laboratory of Harvard University and was then appointed Director of the Allis Lake Laboratory at Milwaukee (1886-89). He was then called to the charge of the department of zoology of the newly founded Clark University, and in 1892 he became head of the department of zoology in another newly founded university, the University of Chicago, which position he held until his death, being thus associated with the whole of the formative period of this institution. He was the first director of the Marine Biological Laboratory, from 1888 to 1908, and established the policy of the institution. He was founder and also editor of the *Journal of Morphology*, the *Biological Bulletin* and the Woods Hole series of Biological Lectures. He was the chief organizer of the American Morphological Society, now the American Society of Zoologists, and was its president for the first four years. He was also a devoted teacher of advanced students many of whom now occupy important academic positions in this country. He was a member of many scientific academies and societies, and received the honorary degrees of LL.D. from Nebraska in 1894 and Biol.D. from Clark University in 1909. Among the subjects that occupied him during a life of intense activity in biological research were the embryology, morphology and natural history of leeches, the morphology of the Dicyemidæ, the embryology of the bony fishes, evolution of color characters in pigeons, natural history of pigeons, hybridization and heredity in pigeons, and studies in animal behavior.

Professor Whitman's life was devoted entirely to scholarly ideals of biological research

which he sought to realize with rare singleness of purpose Not only did he devote himself to personal research with extraordinary enthusiasm and thoroughness, but he had an almost prophetic comprehension of the ways and means for furthering biological investigation, and he was able to secure the cooperation of his colleagues in his enterprises by virtue of a personality that was both singularly winning and compelling In 1887 he founded the *Journal of Morphology*, now in the twenty-second volume, for the publication of research in zoology, and established it at once on so high a plane that it took rank with the foremost journals of zoological research of the world It has since served as model for newer research journals in America In 1888 he was called to be director of the Marine Biological Laboratory of Woods Hole, then newly established, and presided over its fortunes for a period of twenty-one years, during which time it came to be the leading center of biological research in America with a unique and interesting form of organization described more particularly farther on Before any one else in America, he also urged the need of the establishment of an experimental station for the study of problems of evolution, heredity and animal behavior, a "biological farm" as he preferred to call it, and although he was not successful himself in establishing such a station, others have since brought it about In the later years of his life Professor Whitman's personal researches became continually more engrossing and he gradually relinquished his other undertakings into the hands of younger men

Professor Whitman belonged to no narrow field of zoology His scientific interests were broad and they were continually bringing him into contact with workers in other fields He had a very deep interest in all the fundamental problems of biology and we thus find him forming close scientific association with workers in the fields of botany, physiology and psychology as well as in his own field of zoology.

In many respects the Marine Biological Laboratory constitutes Professor Whitman's chief monument Here his ideas had their fullest scope His fundamental idea in the conduct of the laboratory was cooperation, and he succeeded in establishing what has well been called a marine university, in which the ownership and control as well as the conduct of affairs is vested in the body of active scientific investigators The entire body of past and present investigators with few exceptions, constituting the corporation, is the court of last appeal, it elects the board of trustees mainly from its own membership, and the immediate control of laboratory affairs is carried out by the board through their appointive agents, the directors and members of the staff The result has been the realization in our own time and country of the ancient ideal of the university, a republic of scholars.

Such an organization is exposed to dangers internal and external, and though both kinds appeared at various times Professor Whitman always refused to compromise any fragment of his fundamental idea He was therefore often called an impractical idealist by men both within and without the organization Idealist he was, whether impractical or not was none of his concern He often seemed to be most resolute when he stood almost alone as when a safe harbor of refuge for the laboratory appeared within the protecting breakwaters of an established and endowed institution, and nearly all were ready to put into port Yet he preferred liberty and the storm, and all finally stood by him

Professor Whitman instantly recognized creative ability in an investigator, and his appreciation was invariably hearty, and his support ever ready to the fullest extent It is no accident that many of the important discoveries in biology in America during the last twenty years were made at Woods Hole Professor Whitman had early recognized the ability of the workers in question, and had invited them to work at Woods Hole and secured their allegiance to the laboratory, and to himself, for his was a most magnetic personality. Thus he gradually attached to the interests of the laboratory an increasingly strong body of scientific investigators.

Professor Whitman's interest in the teaching side of his profession is fully demonstrated by his organization of teaching as a department coordinate with research in the Marine Biological Laboratory. He steadfastly resisted the influence of some of the investigators in favor of doing away with instruction at the laboratory. He held that teaching exerted an important reflex influence on the body of investigators. He enjoyed and valued the presence of the student element, for whom he had constant sympathy and towards whom he exhibited the utmost friendliness. It has resulted at Woods Hole that the institution, which was made by investigators, has aided in the making of many investigators. Surely no environment more favorable for awakening and stimulating scholarly ambition could be found.

Although Professor Whitman published relatively few papers he nevertheless occupied a commanding position in science. Some of the reasons have already been indicated. His "eye was single and his whole body was therefore full of light", his devotion to scholarship was never open to the slightest shadow of suspicion. He was continuously engaged in his personal research which dealt with the most fundamental problems of biology, and he had accumulated vast stores of data, which we hoped he would live to publish himself. But apparently he could never satisfy himself with reference to the fundamental problems on which his mind was fixed, the grand consummation of his work had not come and he could not reconcile himself to the publication of more or less fragmentary pieces of work. His published papers, mostly short, are models of condensed thought, written in a fine, polished, characteristic style. No less care was devoted to the form than to the substance, and some of his papers certainly will endure as classics of the biology of his time. His activities in connection with the *Journal of Morphology* and the Marine Biological Laboratory brought him into close personal relations with the leading biologists of his time, most of whom learned to value highly his somewhat rarely and deliberately uttered expressions of opinion on scientific problems.

It was, therefore, not only his publications but also his work with his journal, his laboratory and his students, his constant helpful association with other workers and the example of his austere and studious life that brought him recognition. He never permitted himself to be distracted by the confusion of modern life, social or academic, nor diverted from his steadfast purpose by clamor for quick results.

It is impossible for us yet to measure justly the value of such a life to our community; it conveys a much-needed lesson of consecration to the ideals of scholarship, our appreciation of it will surely increase in proportion as time eliminates all the petty details that confuse the picture of a great man's life, and permits its essential nobility to shine forth undimmed.

F. R. L.

December 21, 1910

WITH the death of Charles Otis Whitman America has lost the third of her greatest scholars. Professor Whitman's name belongs with those of William James and Simon Newcomb, not only because of the profound influence he has exerted on the development of zoology in this country by means of his personality, by founding at Woods Hole a unique biological university and by the establishment of the *Journal of Morphology*, but also because of the strength of his character and the greatness of his achievements in science.

His scientific work marks him as a great master, for his finished, published papers are truly masterpieces both of content and expression. In addition to these he had accumulated by long, patient and untiring study an enormous mass of observations on the habits and behavior of pigeons, their phylogeny, inheritance, the origin of species and the progression of species by orthogenesis, independent of natural selection. The general results of this work he had presented from time to time in brief addresses and he was preparing for publication a full report of it, when he be-

came ill Among the results of his scientific work none is more fundamental than his proof of the real course of descent of the pigeons He showed that Darwin had been mistaken in believing the barred type of pigeon to be primitive The evolution was in reality from the checkered to the barred type This discovery led him to the evidence of orthogenetic development in the pigeons and filled in, provisionally at any rate, one of the most puzzling gaps left by Darwin in the problem of evolution. A correct understanding of the direction of evolution of the pigeons gave him, also, the key to the interpretation of the phenomena of inheritance, enabling him to escape the pitfalls which beset the steps of those who do not know the past history and direction of evolution of the forms with which they are working. In addition to this splendid and fundamental work there were, also, long years of study of the embryology and phylogeny of the leeches, the results of which were in part published in his papers on metamerism, the inadequacy of the cell theory of development, and embryology, but in large part remain unpublished, preserved in notes and exquisite drawings It is probable that much of this work and that on the pigeons will be found in such form that it can be published. As a scientist, Professor Whitman was painstaking, self-critical, patient and profound.

It is not, however, of his work as a scientist upon which I wish to dwell, but rather to recall his personality that the memory of it may remain always with us His white hair, his kindling, eager, but thoughtful eyes, his tender, gentle smile, his reticence of speech, his consideration for others, his generosity and courage; his hospitality and graciousness as a host, these endeared him to us all. We shall never forget his simple, unassuming, modest manner, his encouraging sympathy; his ripe and sane judgment. If when he was alone he lived simply, the absorbed student of science, when with his guests in his home he was the embodied spirit of hospitality

His great influence as a teacher was due in part to his fine example and noble ideals, and in part to his habit of picking out young men, who showed any love for science, inviting them to his home, drawing them out, encouraging them and giving them his friendship Many of them he helped financially, and all of those fortunate enough to work near him owe him a debt of gratitude for his sympathy and inspiration Probably no teacher in zoology since Louis Agassiz has exerted so great an influence on young men.

His uncompromising loyalty to principle and his high ideals of work and conduct were among his strongest characteristics. The Woods Hole Laboratory represented his ideal of a laboratory in its organization and spirit Again and again he stood almost alone against his most intimate friends and associates who, frightened at the financial outlook, wished to sacrifice those ideals He invariably prevailed in the long run and events have proved his judgment to have been sound He was a rock upon which all plans which were not shaped in accordance with ideals but rather in accord with opportunity, were sooner or later wrecked This loyalty to ideals was shown, also, in his struggle for a biological farm at the University of Chicago Having outlined an ideal biological farm he refused firmly to give up any feature of it which was essential to that ideal He preferred to wait until the ideal could be had, rather than to compromise on some less perfect scheme

He was always loyal, also, to his ideals of science and no amount of criticism or pressure could induce him to publish one word until he was sure that word was the truth and nothing more or less

He had also an uncompromising and outspoken hatred of shams and half-truths of all sorts. Unreliability in any particular he could never tolerate. He was slow to condemn any man, but once he had weighed him and found him wanting, he never afterwards trusted him. In common with many biologists he had no belief in a future life, but his own life demonstrated in the highest degree, how unnecessary such beliefs are to a truly noble soul.

If there was any one characteristic which

endeared him more than another to all in contact with him, it was his instinctive consideration for others and his warm sympathy. No matter how busy he was, he always welcomed one with a warm clasp of the hand and that charming, tender smile, no matter how long one stayed, it was always too soon to go, no matter how often one came, here was a friend who wished you to come more often. Those in trouble came to him. Every tie of affection, gratitude and respect bound us to him. Every meeting with him was a reinspiration in those splendid ideals of which his whole life was the expression.

We have lost a most loyal and affectionate friend, a great scientist and scholar, a truly noble and simple man.

Albert P. Mathews

SCIENTIFIC NOTES AND NEWS

At the Pittsburgh meeting, December 27–29, 1910, of the Geological Society of America the following officers were elected for the year 1911:

President—W. M. Davis, Cambridge, Mass.

First Vice-president—W. N. Rice, Middletown, Conn.

Second Vice-president—W. B. Scott, Princeton, N. J.

Secretary—Edmund Otis Hovey, New York City.

Treasurer—William Bullock Clark, Baltimore, Md.

Editor—Joseph Stanley Brown, Cold Spring Harbor, N. Y.

Librarian—H. P. Cushing, Cleveland, Ohio.

Councilors (1911–13)—Heinrich Ries, Ithaca, N. Y., and A. H. Purdue, Fayetteville, Ark.

At the recent Pittsburgh meeting of the American Paleontological Society, Professor William B. Scott, of Princeton University, was elected president. The statement in regard to the presidency, taken from the daily papers and printed in the last issue of Science, was incorrect. Other officers of the society are as follows: *First Vice-president*, Arthur Hollick, New York City; *Second Vice-president*, W. D. Matthew, New York City; *Third Vice-president*, Stuart Weller, Chicago, Ill.; *Secretary*, R. S. Bassler, Washington, D. C.; *Treasurer*, Richard S. Lull, New Haven, Conn.; *Editor*, Charles R. Eastman, Cambridge, Mass. Correspondents were elected as follows: Professor G. Alfred Nathorst, Stockholm; Professor E. Koken, Tubingen; S. S. Buckman, England, and Professor Charles Déperet, France.

Professor Ralph S. Tarr, of Cornell University, was chosen president of the Association of American Geographers at its recent meeting in Pittsburgh.

Professor L. B. Mendel, of Yale University, was elected president of the Society of Biological Chemists at the New Haven meeting.

At the annual election of the American Philosophical Society held on January 6 the following officers were chosen for the ensuing year: *President*, William W. Keen; *Vice-presidents*, William B. Scott, Albert A. Michelson, Edward C. Pickering; *Secretaries*, I. Minis Hays, Arthur W. Goodspeed, James W. Holland, Amos P. Brown; *Curators*, Charles L. Doolittle, William P. Wilson, Leslie W. Miller; *Treasurer*, Henry La Barre Jayne; *Councilors* (to serve for three years), Henry F. Osborn, Joseph G. Rosengarten, Edward W. Morley, Henry H. Donaldson.

A marble bust of President Emeritus Eliot, the work of Mr. Louis Parker, of New York, has been placed in the faculty room of Harvard University.

Dr. S. Weir Mitchell, who has been a trustee of the University of Pennsylvania since 1875, has resigned.

The Zoological Society of London has elected as corresponding members Mr. Theodore Roosevelt and Mr. W. H. Osgood, Mr. S. H. Scudder as foreign member.

Dr. H. C. Bumpus, director of the American Museum of Natural History, has been decorated by King Charles, of Roumania, with the grand cross of the commander of the order of the crown.

Sir T. Carlaw Martin, LL.D., editor of the *Dundee Advertiser*, has been appointed director of the Royal Scottish Museum, Edinburgh.

PROFESSOR ARTHUR H. BLANCHARD, of the department of civil engineering, Brown University, has recently been appointed expert and consulting engineer to the United States Office of Public Roads.

PROFESSOR M. V. O'SHEA, professor of education at the University of Wisconsin, has been appointed chairman of the American committee of the International Congress on Childhood and Youth. The next session of the congress will be held in the United States, probably at Washington in 1912.

ARTHUR R. CUSHNY, M.D., F.R.C.S., professor of pharmacology in the University of London, will deliver the first of the "Weir Mitchell Lectures" at the Weir Mitchell Hall in the College of Physicians, Philadelphia, on January 17. His subject will be "Heart Irregularity from Auricular Fibrillation."

DR. GUNTHER JACOBY, privatdocent at the University of Griefswald, and research fellow in philosophy at Harvard University, is giving a course of seven lectures on "Schopenhauer," beginning January 6. The lectures are open to members of Harvard University.

THE municipality of Dôle, Jura, has just voted to buy and preserve the house where Pasteur, on December 27, 1822, was born.

THE *Journal* of the American Medical Association states that as a permanent honor to its founder, who was also for many years its honorary president, the Verein fur innere Medizin und Kinderheilkunde of Berlin has resolved, on motion of Professor Schwalbe, to establish a Leyden lectureship, the lecture to be given annually at the first session of the winter semester, by a speaker selected by the board of directors. This arrangement, which follows the English custom, is the first of the kind made in Germany. A large fee will be paid the lecturer, derived from the interest of the fund of $14,000, established on the seventieth birthday of von Leyden. The rest of the interest on the fund is to be devoted to scientific research under the influence of the society for internal medicine.

THE death is announced at Cincinnati at the age of eighty-eight years of Mr. Benn Pittman, who with his brother, Sir Isaac Pittman, developed the system of stenography which bears their name, and is also known for his inventions in connection with electrotyping.

THE Sarah Berliner research fellowship for women will be awarded for the second time this year. This fellowship, of the value of twelve hundred dollars, is available for study and research in this country and in Europe. It is open to women holding the degree of doctor of philosophy, or to those similarly equipped for the work of further research; it will be awarded only to those who give promise of distinction in the subject to which they are devoting themselves. Applications must be in the hands of the chairman of the committee, Mrs. Christine Ladd Franklin, 527 Cathedral Parkway, New York, by February 1. This fellowship was awarded two years ago (it is given only every two years) to Miss Caroline McGill, Ph.D., who was a member of the teaching staff of the University of Missouri. Miss McGill has spent a year in Europe, chiefly at the Naples Zoological Station.

DR. A. D. GABAY, of New York City, has presented to the American Museum of Natural History a collection of ground and polished shells from California and Japan. These specimens with their convolutions and superb nacre make objects of great beauty. They will be installed in certain sections of the hall of mollusca, illustrating the economic and ornamental uses of shells. The museum has also received, as a gift from Mr. D. C. Staples, a collection of archeological and ethnological material which comes from the provinces of Esmeraldas and Manabi in the extreme northern part of Colombia, South America.

ACCORDING to *Nature* a new zoological garden in course of construction by Mr. Carl Hagenbeck in the grounds of the Villa Borghese, Rome, was expected to be opened on January 1. The grounds, which comprise twenty-eight acres, lie outside the old walls to the northward of the city, and it is stated

that more than $200,000 has been already spent on them, while the animals, some 1,400 in number, represent $50,000. As at Stellingen, cages have been to a great extent dispensed with, deep ditches and scarped cliffs serving to confine the animals, which thus appear to be at liberty.

CONSTRUCTION has begun upon the new Boston Psychopathic Hospital, which has been planned by the Board of Insanity, in accordance with an act of legislature, to receive, observe and treat the acute mental patients of the metropolitan district in Massachusetts. The hospital will be operated by the Boston State Hospital trustees, who have appointed Dr. E. E. Southard director. The institution is planned to contain one hundred beds and embodies the main features of the modern general hospital as well as special therapeutic features appropriate to mental disease. A wide scope is expected for the out-patient and social-service departments. Other districts in the state may in time develop similar psychopathic hospital units, which will take their place alongside the hospitals, asylums and colonies as special clearing-houses and therapeutic establishments for the acute cases of mental disease in each district. In the psychopathic hospitals emphasis will naturally be laid on investigations, both psychic and somatic, into the nature and causes of mental disease.

A BILL to make Paris official time coincide with Greenwich time was presented, as we learn from *Nature*, to the French senate on December 21. The bill was passed by the chamber of deputies several years ago, and has been approved by the senate committee and by the cabinet, so that in all probability it will become law. Paris time is 9m. 21s. ahead of Greenwich time, and upon the day prescribed by the law, the clocks indicating official time in France will be put back by that amount. By the adoption of the change, France will be brought into the international system of standard time reckoning which is now followed in the United States and in most civilized countries. On this system, the hour of each successive fifteen degrees of longitude, reckoning from the Greenwich meridian, is used for the standard time; hence the difference in time in passing from one zone to another is always an exact number of hours.

AT a meeting of the Paris Academy of Medicine held on December 13 the list of the prizes awarded during 1910 was read out by the secretary, M. Weiss. According to the *British Medical Journal* they include the following. The François-Joseph Audiffred prize ($4,800) was not awarded, but sums of $200 were granted to MM. Xavier Delore and André Chalier, of Lyons, for their work on tuberculosis of bone, by way of encouragement, in the same way a sum of $100 was given to M. Jules Lemaire, of Paris, for his researches on the skin reaction to tuberculin, especially in children. The Baillarger prize ($400) was awarded to Dr. Gabriel Doutrebente, of Tours, for his work on the medical organization of lunatic asylums. The Prix Barbier ($400) was divided between Dr. Maire, of Villejuif, for a memoir on the colonization of the epileptics of the Seine Department, and Dr. E. Sacquépée, of the Val-de-Grâce Military Hospital, for his notes on paratyphoid infection. The Boggio prize ($875) was awarded to Dr. Rappin, of Nantes, for his researches on a method of vaccination and immunization against tuberculosis. The Adrien Buisson prize ($2,000) was awarded to Drs. de Beurmann and Gougerot, of Paris, for their work on sporotrichosis; the Campbell-Dupierris prize ($450), to Dr. M. Jungano, of Naples, for a memoir on the flora of the urinary apparatus, normal and pathological; the Théodore Herpin prize ($600), to Dr. Félix Rose, of Paris, for a work on apraxia; the Huguier prize ($600), to Dr. Salva Mercadé, of Paris, for an essay on cysts and abscesses of the uterus; the Laborie prize ($1,000), to Dr. H. Dominici, of Paris, for his work on the treatment of malignant tumors with radium; the Louis prize ($600), to MM. P. Emile Weil, F. Lévy, and G. Boyé, for a paper on internal hæmostatic methods; the Meynot prize ($500), to Dr. Louis Balden-

weck, of Paris, for an anatomical and clinical study of the relations between the internal ear and the point of the petrous bone, the Gasserian ganglion, and the sixth pair of cranial nerves. The Orfila prize ($1,200), for the best essay on the purification of town water after use, and of polluted factory waters, was divided between MM Edmond Rolants, E. Boullanger, Léon Massol and Félix Constant. The Perron prize ($750) was divided between M. Albert Frouin, of Paris (on the possibility of keeping alive animals after complete removal of the thyroid apparatus, by the addition of calcium salts or magnesium to their food); M Gernaro Sisto, of Buenos Aires (the cry of sucklings and hereditary syphilis), and MM. Noel Fiessinger and Pierre Louis Marie, of Paris (notes relating to the protease and lipase of leucocytes) The Saintour prize ($875) was awarded to M Gabriel Petit, of Alfort, for a contribution to pathological anatomy and pathogeny of tumors of the breast; the Tarnier prize ($875) to M. Audré Delmer, for a contribution to the study of auto-intoxications of pregnant women and female bovine animals

THE statistics of coal production as collected jointly by the United States Geological Survey and the Bureau of the Census show that in 1909 the output amounted to 459,-209,078 short tons Compared with the record for 1908, when the production amounted to 415,842,698 short tons, the record for 1909 shows an increase of 44,039,650 short tons, or 10 per cent. All of the gain was in the production of bituminous coal, which increased from 332,573,944 short tons in 1908 to 378,-551,024 short tons in 1909—a gain of 45,977,-080 short tons. The production of anthracite in Pennsylvania decreased from 74,347,102 long tons (equivalent to 83,268,754 short tons) in 1908 to 72,015,222 long tons (equivalent to 80,658,049 short tons) in 1909. Pennsylvania made the largest increase in the production of bituminous coal, showing a gain of 20,666,288 short tons, from 117,179,527 short tons in 1908 to 137,845,815 tons in 1909. West Virginia for the second time in its history exceeded Illinois, and became the second state in the production of coal, the former having an output in 1909 of 51,446,010 short tons, and the latter an output of 50,970,364 short tons. West Virginia's production increased 9,548,167 short tons over 1908 The output in Illinois, which stood third in rank, increased only 3,310,674 Ohio retained its position as fourth in rank with a production in 1909 of 27,919,891 short tons, against 26,-270,639 in 1908 Indiana, which in 1908 supplanted Alabama as fifth in rank, strengthened its position in 1909 by an increase of 2,566,809 tons, from 12,314,890 tons in 1908 to 14,881,699 tons in 1909, while Alabama gained 2,099,317 tons, from 11,604,593 tons to 13,703,910 tons Other significant increases were in Colorado, 1,087,773 tons, Wyoming, 890,995 tons, Kansas, 734,270 tons; Montana, 640,082 tons, Iowa, 594,052 tons, and Washington, 551,463 tons Georgia, Idaho, Maryland, Michigan, Missouri and Texas showed a smaller production in 1909 than in 1908, the total decreases amounting to about 750,000 tons

Nature quotes from the *Aeronautical Journal* for October the announcement that the council of the Aeronautical Society had conferred the gold medal of the society on Mr. Octave Chanute, consulting engineer, of Chicago, shortly before his death Born in Paris in 1832, Chanute trained as an engineer in America, where his professional duties involved the construction of numerous railways and bridges, including consultative duties connected with the New York elevated railway, wood preservation was also his specialty From 1874 onwards Chanute became interested in the problem of aviation, and not only did he make numerous experiments with models, but shortly after, or perhaps simultaneously with, Lilienthal and Pilcher's experiments in Europe Chanute took up the practical realization of gliding flight in America in collaboration with Mr. Herring and Mr. Avery. A large number of glides were made with different types of glider, commencing with a model based on the descriptions of Le Bris's historic "Albatross," and including

gliders with a large number of superposed planes, but the type finally adopted was a biplane glider furnished with a smallish balancing tail Although balance was, as a rule, maintained by moving the body, Chanute embodied in his apparatus the principle of a flexible framework, which thus paved the way for the Wright Brothers' "warping" devices and similar arrangements for the recovery of balance and counteraction of instability, which form such a noteworthy feature of modern aeroplanes The glides made with his machines were remarkably successful, and, the practising grounds being among sand dunes, no fatalities ensued Chanute was the author of a number of papers and reviews dealing with the flight problem, and the Wright Brothers, the late Captain Ferber, and numerous other aviators were indebted to him for much valuable assistance

The following statement, concerning the University of Wisconsin, appeared in the republican party platform of that state

> We are proud of the high eminence attained by our state university We attribute its advancement both to the able and courageous guidance of its president and faculty and to the progressive and enlightened character of the citizenship that sustains it We commend its work, illustrated by what has been accomplished in agricultural and dairy affairs, conserving our natural resources which have effected a saving of millions of dollars annually to the people of our state We also commend its investigations for the improvement of the relations of men to one another We regard the university as the people's servant, carrying knowledge and assistance to the homes and farms and workshops, and inspiring the youth toward individual achievement and good citizenship. We recognize that its service to the state, through investigations in agriculture, industrial and social institutions, depends upon its freedom to find the truth and make it known, and we pledge the republican party to the policy of academic freedom so well expressed by the board of regents in 1894, when they declared "Whatever may be the limitations which trammel inquiry elsewhere, we believe that the great State University of Wisconsin should ever encourage that continual and fearless sifting and winnowing by which alone the truth can be found."

UNIVERSITY AND EDUCATIONAL NEWS

An alumnus, who does not wish his name disclosed, has given $100,000 to the University of Pennsylvania for the endowment of a chair of physiological chemistry. It will be known as the "Benjamin Rush chair of physiological chemistry" Dr Alonzo E Taylor, formerly of the University of California, will be the first occupant of the chair

The University of Vermont has received $67,965 from the Rockefeller Foundation, representing the first instalment of a gift of $100,000 made to the university on condition that an additional $400,000 be raised. The $400,000 has now been subscribed and the amount $271,000 has been collected The half million dollars is to be added to the endowment fund for the general uses of the university

Mr William Blodgett has given to Columbia University two farms near Fishkill, N. Y., to be used in connection with the work in agriculture.

The mining engineering building of the University of North Dakota is being enlarged and the interior remodeled in response to an imperative demand for more room. The roof has been raised, materially adding to the light, floor space and utility of the technical museum Adjoining the museum, which is in the center of the building, there is to be at one end a large preparation room for the curator and at the other a mineral stock room. The laboratories on the first and second floors have been readjusted to provide better facilities for the classes in analytical chemistry and metallurgy as well as for research work in ore treatment, coals and clays. The newly-established ceramic department is being equipped with general clay working and pottery machinery.

Columbia University, according to the official catalogue which has just been published, has this year a registration of 7,429 students. The vast majority of these are in the graduate and professional faculties, the undergraduate and scientific departments having a total registration of 1,456. Nearly every department of the university shows an increase of

from 5 to 20 per cent The academic department has 732 students as compared with 636 a year ago. The medical school, which for the first time required more than a high-school training for admission, has practically the same number of students as it had a year ago, 316 men fulfilling the requirement of two years' college work having entered the school The number of officers and instructors is the largest in the history of the university, numbering 761, including the emeritus professors, of whom there are 16 The newly-appointed professors include William B Fite and Herbert E Hawks, in the department of mathematics, Walter Irvine Slichter, electrical engineering, George V Wendell, physics, and Milton C Whitaker, industrial chemistry

DR EDGAR F SMITH, professor of chemistry in the University of Pennsylvania, became provost on New Year's Day, succeeding Dr Charles C Harrison, who had held this office for seventeen years Dr Smith will continue to lecture on chemistry

PROFESSOR G R THOMPSON, professor of mining, University of Leeds, has been appointed professor of mining at the South African School of Mines and Technology, Johannesburg, and principal of the college

PROFESSOR GUIGNARD, who has served for fifteen years as director of the Paris School of Pharmacy, has resigned his appointment and is succeeded by Mr Henry Gautier, professor of mineral chemistry at the school

THE professors of the Paris medical college have nominated Dr Dejerine, professor of medical pathology, to the clinical chair of diseases of the nervous system at the Salpêtrière. This position, once held by Charcot, was recently occupied by Professor Raymond, who died last September.

DISCUSSION AND CORRESPONDENCE

INORGANIC NOMENCLATURE

IN the issue of SCIENCE for December 9 appeared an article on the nomenclature of the acid phosphates The author, R E B McKenney, pointed out the difficulty of identifying these from the trade names, and suggested more exact names as primary, secondary and tertiary or, better, mono-, di- and tri-potassium phosphates While the change would be a step in the right direction it fails with salts of the polyvalent metals; for the mono-calcium salt would correspond to the di-potassium and thus the confusion would be perpetuated It appears to the writer that a more scientific method would be to indicate the number of replaceable hydrogen atoms (per molecule of acid) present in the salt Thus K_2HPO_4 and $CaHPO_4$ would be named mono-hydrogen phosphates while KH_2PO_4 and $CaH_4(PO_4)_2$ would be the di-hydrogen phosphates The normal phosphates could then be designated as such or simply as phosphates

In this connection I would call the attention of chemists, manufacturers and printers of chemical names to the need of a thorough revision of inorganic nomenclature It is still common to hear and read the names potassic hydrate for potassium hydroxide and sodic carbon for sodium carbonate, the hydrogen (acid) carbonates are called bicarbonates because in making them two equivalents of the acid are required for each equivalent of the base But modern chemistry is founded on molecular rather than equivalent quantities and a bicarbonate should mean, therefore, two carbonate (CO_3) radicals in the molecule of the salt Besides, the bichromates are not acid salts at all in the sense of containing replaceable hydrogen atoms Likewise the percarbonates, persulphates and permanganates do not follow the nomenclature of the perchlorates, perbromates and periodates Also the dioxides and peroxides are named with no discrimination as to differences in constitution.

Has not the time come for scientific men to be exact and scientific in the matter of chemical nomenclature, and to demand of manufacturers the use of names which shall indicate the composition of the material designated? And would it not be well for section C of the American Association, or the American Chemical Society, to appoint a permanent committee on inorganic nomenclature to

the end that all chemical names shall be understood, because they indicate exact composition?

COASTAL SUBSIDENCE IN MASSACHUSETTS

To the Editor of Science: While Professor D W Johnson has clearly shown in the November 18 issue of Science that there are certain factors which produce fictitious appearances of coastal subsidence, chief of which is the irregular height of the tidal wave due to the varying character of the shore, there are a number of marks of subsidence on the Massachusetts coast which it is not probable can be so explained For example, near Misery Island, Beverly, stumps of forest trees appear in place at a depth of twelve to fourteen feet below low tide

The striking example given by Professor Johnson of the fictitious appearance of coastal subsidence at Scituate proves also, it seems to me, that subsidence has really been going on The very fact that the level of the inside marsh was several feet below the outside level of high tide showed how much the land had sunk since the mouth of the North River had been nearly closed A very similar state of affairs exists in the region of the Norfolk Broads in the eastern part of England Here, in the same way, the land is slowly sinking, but, owing to the silting up of the mouths of the Yare and the Bure rivers, aided by dyking, the tides have been largely excluded, the marsh has become fresh and has so long ceased to build up that it is below the level of high water outside, and there is danger of the sea breaking through the sand dunes and, as at Scituate, drowning out the region.

CALENDAR REFORM

To the Editor of Science: I read with interest Professor Chamberlin's suggestions for the reform of the calendar, in the current number of Science, November 25. It happens that I had thought of a scheme the same as that of Professor Chamberlin in all essential features, but was led to abandon it before publication because I considered that its disadvantages outweighed the advantages.

The advantages of the seasonal division are very slight The scheme would suit conditions here as well as the present arrangement. In Great Britain, however, the winter begins in November, spring in February, etc. Hence Professor Chamberlin's arrangement with winter beginning in January would not suit conditions and would not be accepted. The earth receives the smallest amount of heat and light at the winter solstice, and neglecting lag this should be midwinter. To call it the beginning of winter as astronomers do, is to allow 45 days lag To call January 1 the beginning seems to be allowing 55 days lag, not 10 as stated by Professor Chamberlin This lag varies so much in length with latitude and local conditions that it does not appear that any division of the months into seasons will be universally satisfactory

The desirability of a year divisible into quarters is unquestioned. But let us see the disadvantages of the scheme. A man who pays rent, for instance, would find his rent due in the first quarter on the first of the month, say. It would be due the Monday of Easter week, on the twenty-second of the month in the second quarter, fifteenth in the third and the eighth in the fourth. Likewise with monthly salaries and, in fact, all business done by the month. A promissory note dated February 15 due in two months would be due April 8, but if due in one month, March 15, or if due in nine months it would be due October 22. If due in eight months, on the first day of Gregorian week. Likewise, in finding the interval in days between two days we should always need to be on guard against omitting or including wrongly one of these weeks. This problem is a very common one in business. Since the suggestion has been made, there will be no difficulty in multiplying these illustrations indefinitely. When we compare this complexity with the simplicity of the same problems in the regular 13 months of 28

days we see how much is lost. These same objections of course apply, but with less force, to the scheme of Reiminghaus, July 29.

Professor Chamberlin's plan would cause the month to be abandoned as a unit of time for business, and force us to use the week or day

It is true that the same objections may be raised to the 13-month system if we use a quarter as a unit, that is, a quarter from February 15 would be May 22, two quarters, August 1 (assuming the extra month in the middle of the year) But withal this is simpler Moreover, when we compare the amount of business done by the quarter with that done by the month and day we see which should have the greater consideration in constructing a simple calendar

I feel sure that these objections could not have occurred to Professor Chamberlin

INTERNATIONAL CONGRESSES

TO THE EDITOR OF SCIENCE: At the request of the Swedish geologists the International Geological Congress took place this year instead of 1909 This year was also that in which the International Zoological Congress naturally fell to be held. Since, for the convenience of university workers, these congresses are usually held at the same time of year, and since they, with their excursions, now extend over a considerable period, especially in the case of the Geological Congress, it was almost inevitable that the times of the meetings should clash. This may not affect a large number of participants, but it is rather hard on paleontologists, whose interests lie in both camps, and who, even with the aid of the aeroplane, can not be in two places at once. I should not trouble you with a complaint about what appeared to be inevitable this year, were there not signs of the same difficulty recurring in perpetuity, unless a protest is at once raised. As a matter of fact, the committee of "Paleontologia Universalis," when it met at Stockholm, forwarded to the council of the congress a request that this interference should be avoided in future. That protest seems to have been without result. If so, in 1913 the paleontologist will again find himself summoned either by duty or desire to opposite quarters of the globe

SCIENTIFIC BOOKS

Monograph of the Okapi. By SIR E RAY LANKESTER, K.C B, M A., D.Sc, F.R S, etc Atlas (of 48 plates) London, printed by order of the Trustees of the British Museum 1910. 4to, pp i–viii, plates 1–48

Few events of recent years have aroused the interest of naturalists so much as the discovery of the okapi. It was sufficiently surprising that so large and strikingly marked an animal should have remained undiscovered for so many years, that it should prove to be related to a group now extinct increased the interest in the okapi and the known facts relating to it were promptly given in papers of scientific or popular interest, and more comprehensive memoirs were planned by those fortunate enough to be in the way of securing material Among them was the present monograph, commenced by E Ray Lankester while he was director of the British Museum and which having been delayed by many causes is a monograph in name only It consists of 48 plates without text and it is stated in the preface that it is doubtful if the accompanying text will be issued, the need for any having been lessened by the appearance of Fraipont's monograph in 1907, and de Rothschilds and Neuville's paper during the present year, 1910 Fraipont's memoir, by the way, was begun by Forsyth Major, whose interest seems to have flagged after having had a number of illustrations prepared. The plates in Lankester's monograph comprise dorsal, lateral and palatal views of various skulls, drawn on a liberal scale, one third to one half natural size, and these are sufficient to afford good terms of comparison with other material. There are also views of the entire animal including one of a living calf, and plates illustrating variations in the vertebræ. As the explanations of the plates are very full a

pretty clear idea may be obtained of the character of the okapi itself, the great lack being detailed comparison of the okapi with other ungulates, living and extinct, and consequently, the absence of information regarding the relationships of the animal A large number of illustrations are devoted to variations in the striping of the fore and hind legs, practically no two animals being alike in this particular Some of these figures are from mounted specimens, and some from bandoliers made of okapi skin, including the first two obtained by Sir Harry Johnston, which Dr. Sclater took to be from a zebra and in this belief described the animal as *Equus johnstoni*, on February 5, 1901, the generic name *Okapia* being given by Lankester later in the same year *Okapia liebrechtsi* was described by Forsyth Major in 1902 and subsequently Lankester based a third species, *O erichsoni*, on a peculiarity shown in the frontal hair whorls of an individual There is, however, little doubt that there is but a single valid species

It was a theory of Professor Marsh that good illustrations were really more important than text, since they showed facts that might be used by any one while the text would consist naturally more or less of the opinions of the writer From this viewpoint the volume under consideration will be appreciated by all It is also valuable as a study in individual variation, no two specimens of the okapi being quite alike either in external appearance or internal structure And while Lankester qualifies his remarks on these points by saying that he has not had the opportunity of examining a similar amount of material of any other species of large wild animal there can be little doubt but what the okapi is really exceptional in the amount of individual variation it presents

F A. LUCAS

Reproduction artificielle de minéraux au XIXe siècle By P N. TCHIRWINSKY Kief, 1903–1906 8vo Pp. lxxxviii + 638, 117 figures and 11 portraits

A very comprehensive work on the artificial production of minerals has recently been published in Russia by Professor Tchirwinsky The work contains 177 figures of various crystals, some fifty of which were produced by the author himself, and also eleven portraits of scientists who have worked on synthetical minerals

While covering the same ground as the earlier treatises on the subject by Fuchs (1872), Fouqué and Michel Lévy (1882), Bourgeois (1882) and Meunier (1884), as well as the chapters devoted to this subject in the works on mineralogy by Doelter (1890) and Brauns (1896), the writer has not only added a very complete record of the rich and important results of scientific research in this department during the last two decades of the past century, but has revised and rearranged the earlier material, and corrected several errors in the references The critical remarks with which he accompanies his résumés are to a considerable extent based upon his own experiments

The work falls into two parts, a general and a special part At the outset the writer explains that he uses the term "artificially produced minerals" only in regard to those which are produced in the laboratory, and not in reference to such as may be fortuitously produced, as for example, the diamonds which have been found in steel, or minerals formed upon metal ornaments, etc., that have been long buried (pp 13–15) In this connection the author cites the words of St Meunier, that the convalescent who two thousand years ago cast a coin into a mineral spring whose waters had cured him, little knew that he was initiating a geological experiment[1]

The writer then proceeds to describe the more important kinds of apparatus employed in the laboratories for the artificial production of minerals, many of these are figured (pp. 15–24). He next passes to the consideration of the methods used for measuring artificial crystals (pp. 25–27) The fact that in a large number of cases these crystals are exceedingly small and can only be viewed through the

[1] Page 14, note St Meunier, "Méthodes de synthèse en minéralogie," Paris, 1891, p 55

microscope, makes it very difficult to measure them accurately and to determine their exact form As the study of artificially produced minerals would be greatly facilitated by having an approximately complete collection in one place, the author expresses the wish that specimens of such minerals produced in various countries might be sent to the Société Minéralogique de France, in Paris; these, added to the large number of such minerals now in the Collége de France, etc, would make an exceptionally complete collection An atlas of colored plates figuring the most important of them might then be issued by the French society, and this would serve to supply the lack of such material in many collections (pp 27, 28)

The aims of mineral synthesis are then presented at some length (pp 28-124) The light thus thrown upon the question of the natural formation of minerals is noted in the case of metalliferous deposits (pp 30-33), dolomites (pp 33-37), contact minerals (pp 37-40), the formation of the diamond (pp 43, 44), etc This is followed by sections treating of the physical and chemical conditions influencing the form of crystallization assumed by various minerals and the order of their production, and also of their systematic classification, as explained or furthered by the results attained in artificial reproduction (pp 49-119). It would be impossible, within the limits of this article, to do more than note the convincing demonstration of the great service rendered by the synthetic method in the solution of many difficult problems Several mineral forms have been produced in this way in a purer state than that in which they naturally occur, in some instances forms not yet discovered have been produced, thus serving to fill up gaps in the different classes. In other cases where it is difficult or impossible to make an accurate analysis of the natural specimens, the synthetic products have supplied this deficiency, as in the case of the chalcomenit from Argentina which was reproduced by C Fridel and E. Sarradin in 1881 (p 104) A very full list of the spinel crystals obtained by E. Ebelman is given (pp. 78-81)

While the scientific value of these artificially produced minerals can scarcely be overestimated, their practical value is very slight (p 120) As the author notes, only the ruby has been reproduced in a form and size that renders the specimens to a great extent the same as the natural stones, and yet even in this case—apart from the fact that they are not products of nature, but of art—a careful examination reveals certain peculiarities, due to the method of production, which differentiate them from the natural rubies

In the special part of the work (pp 127-496) the very rich and complete material has been arranged in approximately chronological order, all the minerals produced by a given experimenter being grouped together under his name This arrangement has its advantages, although it obliges the reader to seek in different parts of the book for information regarding any one mineral This search is, however, facilitated by very complete indexes A supplement (pp 497-638) contains material omitted for one reason or another from the main work, here the arrangement is according to mineralogical classification

Tchirwinsky has never been sympathetic with Moissan at any time or in this work. He has said, for excellent reasons

The volume contains nine excellent portraits, the list of which is here added

Eilhard Mitscherlich Professor of chemistry in the Berlin University, member of the Berlin Academy of Sciences, d 1863

Henri Sainte Claire Deville Professor of chemistry in the École Normale and in the Sorbonne, member of the Académie des Sciences, d. 1881

L Troost Professor of chemistry in the Sorbonne, member of the Académie des Sciences.

F A Fouqué Professor of the natural history of inorganic bodies in the Collége de France, member of the Académie des Sciences Paris

A. Michel Lévy Member of the institut, general inspector of mines Paris

Charles Friedel. Professor of mineralogy and of organic chemistry, d 1900 Paris.

Etienne Stanislas Meunier Doctor of Sciences, laureate of the institut Paris

Constantine Demetrius Chroustchoff. Professor of mineralogy, crystallography and petrography in the St Petersburg Academy of Medicine St. Petersburg

A B Fr af Schultén Professor of chemistry in the Alexander University at Helsingfors

SCIENTIFIC JOURNALS AND ARTICLES

The December number (volume 17, number 3) of the *Bulletin of the American Mathematical Society* contains the following articles: Report of the September meeting of the San Francisco Section by C. A Noble, "A new proof of the theorem of Weierstrass concerning the factorization of a power series," by W D MacMillan, Review of Kowalewski's Determinantentheorie, by Maxime Bôcher, Review of Wright's Invariants of Quadratic Differential Forms, by L. P. Eisenhart, Review of Volume 4 of Sturm's Geometrische Verwandtschaften, by Virgil Snyder, "Notes", "New Publications"

The January number of the *Bulletin* contains Report of the October meeting of the Society, by F N Cole, Report of the Konigsberg meeting of the Deutsche Mathematiker-Vereinigung, "On the saddlepoint in the theory of maxima and minima and in the calculus of variations," by R G D. Richardson; "Note on identities connecting certain integrals," by Louis Ingold, Review of Poincaré's Gottingen Lectures, by G D Birkhoff, Review of Lorentz's Theory of Electrons and of Wien's Elektronen, by E. B Wilson, "Shorter notices": Lilienthal's Differentialgeometrie, Volume 1, by E J Wilczynski, Boehm's Elliptische Funktionen, Part 1, by L. W Dowling, Dingeldey's Sammlung von Aufgaben zur Anwendung der Differential- und Integralrechnung, by E W Ponzer, Murray's Calculus, by W R. Carver, Crabtree's Theory of Spinning Tops and Gyroscopic Motion, by E W Brown, Loney's Dynamics of a Particle and of Rigid Bodies, by W. R Longley, "Notes", "New Publications"

The *Journal of Experimental Medicine* begins its thirteenth volume with the announcement that it will hereafter be issued once a month instead of once in two months as heretofore. Two volumes will thus be issued each year. No change is made in the price of subscription. Dr. Benjamin T. Terry takes the place of Dr Eugene L. Opie as the associate of Dr. Simon Flexner in the editorial control of the journal.

SPECIAL ARTICLES

VISUAL SENSATIONS FROM THE ALTERNATING MAGNETIC FIELD[1]

The experiments reported by S. P. Thompson in the *Proceedings of the Royal Society*, B, 82 (557), pp 396 ff., are of great importance, especially in view of the negative results which have been obtained in the several earlier attempts to arouse sensations by subjecting the head to the influence of a magnetic field Previous experimenters seem, however, to have used direct current, while Thompson used alternating current

Thompson obtained his magnetic field from a coil of 32 turns of stranded copper conductor of 2 square inch equivalent cross section, the coil having an internal diameter of nine inches and a length of eight inches. This coil was supplied with 50-cycle alternating current, the maximal amperage being 180 The subject's head was inserted in the coil, and under these conditions Thompson and several others were able to obtain flickering light sensations which were especially conspicuous in the peripheral part of the visual field The flicker was noticed even when the eyes were open Certain subjects reported sensations of taste also

It occurred to me on reading Thompson's report that the visual phenomenon might well be due to idio-retinal light, under the suggestion of the hum of the coil due to the alternating current, and as Thompson mentions no specific checks or precautions in his procedure, it seemed worth while to repeat the ex-

[1] I am indebted to the persons mentioned in this paper for their interest and participation in the experiments, and especially to Professor J. B. Whitehead and Mr Henry C. Louis, without whose cooperation the experiments would have been impossible.

periment. Professor Whitehead readily agreed to cooperate with me, and the first tests were made in his laboratory and under his personal supervision.

The coil used had 27 turns of a cable consisting of 37 copper wires (each 082 inch in diameter) equivalent to 250,000 circular mils. The coil was approximately 8 inches long, and elliptical in cross section, the internal diameters being 10.5 inches and 9 inches. With this coil no part of the subject's head or face touched the internal surface, a condition which we could not always attain with a coil of circular cross section and 9 inches internal diameter, which we first tried The coil was suspended from the ceiling by ropes, so that the subject could sit in a chair with his head inside the coil. The transformer available forced approximately 200 amperes of 60-cycle A C through the coil, the potential drop between coil terminals being slightly over 12 volts. This gave a field of 5,400 ampere turns, against 5,760 maximal in Thompson's experiment.

On first trial I distinctly perceived the flicker Dr Anderson, Dr. Cowles, Dr Essick and a student also perceived it on first trial Dr Watson was uncertain on first trial, but on second trial perceived the flicker, although not very distinctly until after several trials Dr. Jennings, Dr Whitehead and several others perceived absolutely nothing, even after careful trials. It still seemed to me possible that idio-retinal light and suggestion were at the bottom of the phenomenon and therefore Dr. Watson and I carried out some careful tests in which suggestion was excluded to the fullest possible extent, which tests showed conclusively that my suspicion was unfounded. In these tests the transformer rested on a table close beside the coil, so that the loud noise of the former completely drowned the hum of the latter The current could be switched off the coil, and on resistance carrying practically the same amperage as the coil, so that in either case the transformer noise was the same A telephone receiver connected with the transformer was hung on the coil, emitting a loud noise whether the current was on the coil or on the resistance. For further precaution the subject's ears were plugged up as well as was possible Under these conditions, where there was absolutely no way of telling by the sound whether the current was on or off the coil, each of us was able to identify the flicker with absolute precision

Several subjects noticed a twitching of the eyelids, when the head was in the coil. This was noticed especially by two of the subjects who were unable to perceive the flicker, and who thought it probable that the muscular sensations were at the base of the phenomenon. They were asked to report on the twitching, while the current was being turned now on the coil, now on the resistance, and it was found that the twitching occurred just as strongly when there was no current on the coil as when there was current

Those who perceived the flicker found it becoming less distinct after a minute or even less of stimulation, and found it restored by a few minutes' rest

The flicker was best perceived with the eyes closed or with the room darkened, but was noticeable with the eyes open if the room was not too brightly lighted. The interior of the coil furnished a fairly dark background

I made tests with both positive and negative after-images but could not find that the flicker affected them in any way The flicker was strongest in the peripheral visual field, and possibly did not affect to any considerable degree the central portion of the field, in which were the after-images

It was clear, as a result of these tests, that the phenomenon was really a matter of visual sensation, and that we were dealing with threshold values, it needed only higher intensity to make the flicker visible to all subjects Further it seemed to me strongly indicated that current of less frequency would give more intense flicker. Mr. A. E Loizeau, of the Consolidated Gas, Electric Light and Power Company, kindly offered us the facilities of his testing plant, and the coil was accordingly removed thither, and further tests

carried out under the supervision of Mr. Henry O. Louis of the company's electrical engineering department.

We forced 440 amperes of 60 cycle alternating current through the coil, with terminal potential drop of 32 volts. The flicker now became much more distinct than it had been at the lower amperage. Dr. Whitehead, Dr. Jennings and one of the students who before had not noticed any flicker, were present at these tests and now got the flicker very clearly at first trial. Mr. Louis and a number of the electricians also testified to the unmistakable nature of the phenomenon.

With 480 amperes of 25-cycle current (20 volts) a much more striking result was obtained. With my head below the level of the coil, and with my eyes open, the flicker was strongly noticeable, although the room was brightly lighted by afternoon daylight. The whole visual field quivered as if illuminated by a rapidly intermittent light. Several other subjects made a similar observation, although in some cases the flicker was noticed only in the less illuminated parts of the visual field, as where shadows fell in the room. With the head inside the coil the flicker was so pronounced as to be intensely disagreeable. The flicker seemed to me slower than with the 60-cycle current, and Mr. Louis and one of his assistants found the same apparent difference. Others were uncertain as to this point. The flicker with 60-cycle current had seemed to me to differ in character from ordinary visual flicker; it was odd, or novel in an indefinite way, but the flicker with 25-cycle current seemed quite like ordinary rapid flicker. This difference I am inclined to explain by the fact that normally a flicker of 60 per second is imperceptible, hence such a flicker seems unusual when produced under these abnormal conditions.

With the 200-ampere current, I had found that with the head either above or below the coil, with the face turned either upward or downward, practically no effect was obtained, although in two of these positions the eyes were close to the plane of the end of the coil, and hence in a strong magnetic field. Rotation of the head from one of these positions through 90° (presenting the side of the head to the coil) brought in the flicker distinctly. My observation on this point was confirmed by Dr. Anderson and Dr. Watson. With the stronger currents the effect was much more pronounced. Although some flicker was observed when the occipito-frontal axis was vertical, rotation of the head through 90° caused a great increase. This would suggest that the effect is due to induction currents in the optic pathway, since in the position with occipito-frontal axis vertical, the general direction of the optic pathway is parallel to the lines of force, whereas rotation of the head through ninety degrees brings the pathway across the lines. When the head is inside the coil, the pathway crosses the lines in the most intense part of the magnetic field.

Whether currents induced in the optic pathway excite the occipital cortex directly, or excite the retina primarily, is yet a matter for conjecture. That flicker is produced by alternations faster than the fastest flicker from normal light stimulation is of course no evidence for the non-retinal character of the flicker in question.

I can not say as yet that there is a definite *arousal* of visual sensation by the alternating field; the effect appears more like an alternate intensification and inhibition of whatever sensory process is already in progress. That is to say, if a certain intensity of normal light-sensation or idio-retinal light is present before the current is turned on, the apparent effect of setting up the alternating field is alternately to increase and decrease the intensity of the sensation so that the average intensity is not changed. It is quite possible that further observation will change my opinion on this point.

No sensations other than the visual, which could be connected with the alternating field were noticed by any of us. That there is no after-effect from the stronger fields, I should not like to say at present. I should advise any experimenter to proceed cautiously.

It is very desirable that experiments with a

large range of amperages and frequencies be made, but I am not certain that I shall be able to carry these out in the near future The difficulties in the way of securing adequate control of current when high amperages are used are greater than may appear to the casual reader

KNIGHT DUNLAP

JOHNS HOPKINS UNIVERSITY,

THE GERM CELL DETERMINANTS IN THE EGGS OF CHRYSOMELID BEETLES

PARTS of my papers on "The Origin and Early History of the Germ Cells in Some Chrysomelid Beetles,"[1] and "The Effects of Removing the Germ Cell Determinants from the Eggs of Some Chrysomelid Beetles"[2] have recently been subjected to criticism,[3] which, it seems to me, needs some analysis I have shown in these papers that a disc-shaped mass of darkly staining granules appears at the posterior end of the eggs of certain chrysomelid beetles just before deposition Because of the shape of this mass and its position in the egg, I have called it the "pole disc" During the formation of the blastoderm, those cleavage products which, in their progress toward the periphery, encounter the pole disc granules, gather these about themselves and continue their migration, finally becoming entirely separated from the egg They then lie in a compact group at the posterior end These are the primordial germ cells, they can be traced back into the embryo, where they separate into two groups which become the germ glands The conclusion was reached that the cleavage products "are potentially alike until in their migration toward the periphery they reach the 'keimhautblastem.' Then those which chance to encounter the granules of the pole disc are differentiated by their environment, *i e*, the granules, into germ cells; all the other cleavage products become somatic cells" (1908, p. 21).

It was found to be possible to remove the pole disc from freshly laid eggs by pricking the posterior end with a needle and allowing them to flow out Eggs operated upon in this way produced embryos and larvæ either without germ cells or with only a few This experimental evidence, added to that derived from the morphological study, seemed to prove that the pole disc granules were necessary for the production of the primordial germ cells and, in fact, determined them as such This led to the conclusion that the "granules of the pole disc are therefore either the germ cell determinants or the visible sign of the germ cell determinants" (1908, p 21) Recent experiments give additional evidence When the posterior ends of freshly laid eggs are killed with a hot needle, thus preventing the pole disc from taking part in development, no germ cells are produced in the embryos and larvæ which develop from them

Wieman objects to the term "germ cell determinant" since "the term implies the attribute of certain potentialities that these granules have not been shown to possess" (1910, p 180) He also objects to my hypothesis that the pole disc granules consist of chromatic material extruded by the nucleus of the oogonium, and claims that "the granules of the pole disc consist of particles derived from the food stream of the ovum that form an accumulation of the protoplasm in its posterior part" (1910, p 187) This is no doubt correct I did not attempt to discover the origin of these granules, but concluded that they were of nuclear material because of the derivation of similar substances in the early development of *Ascaris, Cyclops* and a number of insects. According to Wieman, "the granules are not all taken up by the cells in their migration and the greater part of them remains behind after the cells have passed through" (p. 186). This is certainly not the case in the four species of beetles that I have used in my work.

Wieman suggests several possibilities as to the ultimate origin and significance of the pole disc granules These possibilities were

[1] *Journ Morph*, Vol 20, 1909, pp. 231–296.

[2] *Biol Bull*, Vol 16, 1908, pp. 19–26

[3] Wieman, H. L, "The Pole Disc of Chrysomelid Eggs," *Biol. Bull.*, Vol 18, 1910, pp. 180–187

fully considered in my papers as the following quotations will show. Wieman says (p. 186), "The granules may therefore be of the nature of chromatin and actually represent the chromatin of the nurse cells . . " In my paper (1909, p. 274) is this statement, "the granules of the pole disc may be derived from the nuclei of the nurse cells which, in many insects, pass into the early oocytes" Again Wieman remarks (p. 186) "The fact that the pole disc occupies a position between the pole cells and the yolk gives a considerable foundation for regarding it as a source of nutrition for these cells" My suggestion reads as follows (1909, p. 275) "they may hasten the growth at the posterior pole of the egg, and that later they may possibly increase the vigor of the pole cells That the pole cells need special means of nourishment is doubtless the case, for, contrary to the condition in the blastoderm cells, they are at an early period entirely separated from the yolk, and later use up energy in their migration"

Furthermore, Wieman unconsciously admits that the pole disc granules are really germ cell determinants in the following words (p. 186). "If then the pole disc represents a part of the nutritive stream of the ovum that has not been transformed into ordinary yolk, but instead has been reserved to supply the pole cells, the conclusion presents itself that the latter as a result of this special kind of nutrition, undergo a peculiar method of metabolism which differentiates them from the somatic cells"

An account of the significance of the germ cell determinants in chrysomelid beetles and other animals is now in press.[4]

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE THE MINNEAPOLIS MEETING

REPORT OF THE GENERAL SECRETARY

THE sixty-second meeting of the American Association for the Advancement of Science was held at the University of Minnesota, Minneapolis, December 27 to 31, 1910. The registered number of members in attendance was approximately 500, but the actual attendance was probably not far from 1,200. Both in registration and attendance the meeting was an advance upon those of St Louis and New Orleans It also furnished an illuminating answer to the question whether a successful and well-attended meeting can be held in the middle west

All meetings of the sections and affiliated societies were held on the campus of the university, with the exception of the Thursday sessions of the botanists and the entomologists, which were held at the college of agriculture. Three public addresses were held. On Tuesday evening, the retiring president, Dr David Starr Jordan, gave his address, "The Making of a Darwin," in Minneapolis On Thursday evening, Mr W. A. Bryan gave an illustrated public lecture on the Hawaiian volcano Kilauea On Wednesday evening in St Paul, Mr A. B Stickney delivered a public lecture on the subject, "Should Practical Agriculture and the Physical Development of Childhood be Added to the Curriculum of the Public Schools." Of general interest also was the symposium on aviation under the auspices of Section D on Friday, and the unusually well-attended dinner and convention of Sigma Xi on the afternoon of the same day

Section A and the Chicago Section of the American Mathematical Society met for the most part in joint session, with a total of 34 papers. On Friday afternoon they considered the report of the Committee on the Teaching of Mathematics to Students of Engineering. Section B and the American Physical Society met constantly in joint sessions, at which 33 papers were presented. In addition, a general interest session in charge of Section B was held on Thursday morning, while in the afternoon, B and D met jointly for the reading of the vice-presidential addresses.

In accordance with the present plan, Section C held no meetings apart from a session for the delivery of the vice-presidential address. All sessions of the general program

were essentially joint sessions, though under the auspices of the American Chemical Society. Two addresses and 8 papers were presented at the general meetings. Sixteen papers were read before the Division of Agricultural and Food Chemistry, 12 before the Division of Fertilizer Chemistry, 4 before the Division of Pharmaceutical Chemistry, and 8 before the Chemical Education Section. The largest number of papers, 47, was given before the Division of Physical and Inorganic Chemistry, 44 were read before the Biological Section, 27 before the Industrial Chemists and Chemical Engineers, and 17 before the Division of Organic Chemistry.

Twelve papers were presented before Section D in the symposium on aeronautics, and 10 were given on the regular program. Before Section E, the program consisted of 5 papers on Economic Geology, 7 on Structural Geology, 7 on Glacial Geology and 6 on Geography. Section F and the Central Branch of the American Society of Zoologists met regularly in joint session, with a program containing 43 papers. Fifty-eight titles appeared on the programs of the Entomological Society of America and the American Association of Economic Entomologists. The meetings of the Association of Horticultural Inspectors were given largely to reports of committees and to discussions. Five zoological papers were also presented at the meetings of the American Microscopical Society.

Section G, the Botanical Society of America, and the American Phytopathological Society met regularly in joint session, except on Friday morning, when simultaneous sessions of the section and the pathologists were necessary to complete the program. The features were the special addresses before the joint session on Wednesday afternoon, under the auspices of Section G, and the symposium on plant pathology at the College of Agriculture on Thursday, under the auspices of the Botanical Society. An interesting innovation was a conference on botanical teaching at the close of the botanical dinner on Thursday evening. Seventy-one papers were presented at the botanical sessions. The program of the Sullivant Moss Society consisted of 12 papers on mosses, liverworts and lichens. The American Nature-Study Society held three symposia on Friday, devoted to the subjects: "The School Garden as a Nature Study Laboratory," "Natural History Museums in Relation to Nature Study Instruction" and "The Organization of Nature Study."

Section H held no meeting, but the American Psychological Association and the Western Philosophical Association were both in session. The two met in joint session on Thursday, and in session with Section L on Wednesday. Thirty-four papers were presented. Twelve papers were read before Section I. The symposium before Section K was devoted to the subject, "Diseases due to Filterable Organisms." In addition, a number of papers were presented in the general program. Section L met in joint session with the American Psychological Association, for the discussion of the topic, "Educational Psychology," and in joint session with the American Federation of Teachers of the Mathematical and Natural Science to discuss the topic, "Methods of Testing the Results of Science Teaching." The section also held a general interest session on university extension teaching, in addition to the program of 7 reports on investigations in education. The meeting of the American Federation of Teachers of the Mathematical and Natural Sciences was devoted to the reports of committees on various subjects.

The important actions taken by the council at the Minneapolis meeting were as follows:

1. A committee on organization and correlation was appointed, consisting of nine members, of which four were to be members of the council. This committee reported the following recommendations: "The committee recommends to the council that each section, when the corresponding affiliated society is meeting at the same time and place, shall confine its sessions at the annual meeting preferably to half a day or at most to two half days, and that the sectional program shall include the address of the vice-president and a series of papers of general interest prepared by in-

vitation issued by the committee of the section." The recommendation of the committee was adopted, and on motion the council resolved further that it regards with especial favor holding all sessions under the joint auspices of the section and the appropriate affiliated society

2 A resolution was adopted as follows

WHEREAS serious injury and injustice would be done to scientific societies and scientific journals should such societies be forbidden to send scientific journals to members by second class postage

Resolved, that the American Association for the Advancement of Science, meeting in Minneapolis, request the Postmaster General and the Committees on the Post Office of the Senate and the House of Representatives to give careful attention to the effects of any ruling of the department that might limit the advancement and diffusion of science in this country

Resolved, that copies of these resolutions be sent to the Postmaster General and to members of the Committees on Post Office of the Senate and the House of Representatives

The officers of the association were instructed, officially and in the name of the association, to take such steps as will aid in the passage of the Dodds bill

3 The election of fellows of the association was placed upon the basis of professional work in science, in the hope that greater uniformity will thus be secured in the action of sectional committees

4 The usual grant of $200 was given to the Concilium Bibliographicum, and an additional grant of $75 to Professor G. J Peirce for continuing the study of organisms in brines

The general committee voted to hold the next meeting of the association in Washington from December 27 to December 30, and to reaffirm the action contemplating meetings in Cleveland and Toronto for 1912 and 1913 respectively The following officers were chosen for the Washington meeting·

President—C E Bessey, University of Nebraska

Vice-presidents—Section A, Mathematics and Astronomy, E B Frost, Yerkes Observatory, Section B, Physics, R A. Millikan, Chicago University, Section C, Chemistry, F K Cameron, Department of Agriculture, Washington, Section D, Mechanical Science and Engineering, C S. Howe, Case School of Applied Science; Section E, Geology and Geography, Bohumil Shimek, University of Iowa, Section F, Zoology, H F Nachtrieb, University of Minnesota, Section G, Botany, F C Newcombe, University of Michigan, Section H, Anthropology and Psychology, G T Ladd, Yale University, Section I, Social and Economic Science, no election, Section K, Physiology and Experimental Medicine, Dr W T Porter, Harvard University, Section L, Education, E L Thorndike, Columbia University

General Secretary—John Zeleny, University of Minnesota

Secretary of the Council—T S Palmer, Washington, D C

FREDERIC E CLEMENTS,
General Secretary

SECTION A—MATHEMATICS AND ASTRONOMY

As the Chicago Section of the American Mathematical Society held its regular Christmas meeting in affiliation with the American Association, the special program of Section A did not include any technical mathematical papers The "general interest session" of the section was held on Wednesday afternoon This was a joint session of the Chicago Section of the American Mathematical Society and of Section A, and the program of the session consisted of the vice-presidential address by Professor E W Brown, of Yale University, and the papers by F R Moulton and E B Frost, of the University of Chicago

A very interesting feature of the meeting was the joint session of Sections A and D and the Chicago Section of the American Mathematical Society This session was devoted to the report of the committee of twenty, appointed at a similar meeting in Chicago, in December, 1907, on the question The teaching of mathematics to students of engineering. During the evening preceding this meeting members of Sections A, B and D and the Chicago Section of the American Mathematical Society discussed informally questions relating to this report and were afforded excellent opportunities to become better acquainted.

In the absence of their authors the papers by J E Siebel and H. E. Wetherill were read by title. The papers by J. A. Parkhurst and Percival Lowell were read by E. B Frost and Frederick Slocum, respectively. All the other papers of the

following list were read by the authors during the three sessions of Section A.

1 "The Relations between Jupiter and the Asteroids" (vice presidential address), E W Brown

2 "The Contributions of Astronomy to Mathematics," F R Moulton

3 "On some possible Bases for the Spectral Classification of Stars," E B Frost.

4 "Apparent Photographic Star-streams and their Relations to some of the Vacant Regions of the Sky," E E Barnard

5 "Photographic Observations of the Surface of the Planet Mars," E E Barnard

6 "An Integrable Case in the Problem of three Bodies," W D MacMillan

7 "Photographic Position of 127 Stars within Ten Minutes of the Ring Nebula of Lyra," F P Leavenworth.

8. "Preliminary Report on the Evidences of Circulation in the Atmosphere of the Sun, Derived from the Study of Solar Prominences," Frederick Slocum

9 "On the Choice of Standard Stars in Photographic Stellar Photometry," J A Parkhurst

10 "The Oblateness of the Earth," J E Siebel

11 "Dials for Calculations," H E. Wetherill

12 "Parallax of Ring Nebula of Lyra from Photographs taken at the Lick Observatory," B. L Newkirk.

13 "Spectrum of Ring Nebula of Lyra," K. Burns.

14 "The Sun as a Star," Percival Lowell

The addresses by E W Brown and F R Moulton will appear in SCIENCE Abstracts of the other papers follow, the numbers preceding these abstracts correspond to the titles in the list given above.

3. There are numerous possibilities in the selection of a basis for the establishment of a system of stellar classification according to spectra. Emphasis may be laid upon the differences of a physical sort between stars, such as temperature, as inferred from the extension of the spectrum toward the violet, or from measurements of the radiation at different wave-lengths or differences of a chemical sort may be made the criterion, according to the elements found in the spectra. Again, theoretical reasons based upon the dynamics of the case may be regarded as especially important; or deductions from some hypothesis of stellar evolution may be considered as the most logical basis for discrimination. Even the motions of the stars, or the space within which they are found, may have a bearing upon the subject, as, for instance, in the case of the streams of stars recently discovered and lately much discussed

The paper gives a brief general discussion of some of these points, with lantern illustrations of different celestial spectra

4 There are frequently seen, on wide field photographs of the sky, lines of stars either straight or curved, and sometimes in the form of more or less complete ellipses with a brighter star in a focus of the ellipse It is probable that most of these stars are not physically connected, and appear so only by perspective But it does not seem probable that all these appearances are due to fortuitous circumstances alone

Besides these lines and curves of stars, so striking in some parts of the sky, there are apparently broad streams of stars which seem to have a common trend This appearance usually occurs in a very dense region, and resembles that which might be produced by the sweep of a giant broom In some cases these "sweeps" are apparently connected with vacant regions, as if there were a common drift of the stars away from these places A striking case of this kind occurs in *Scutum*, where the appearance is that of streams of stars diverging away from or converging to a vacant region at this point

5 During the opposition of Mars in 1909 efforts were made to secure photographs of its surface features with the 40-inch refractor and a negative enlarging lens made by Brashear For this purpose a yellow color screen, made especially for the work by Mr. Wallace, with Cramer instantaneous isochromatic plates, was used. Though the exposures were short (three or four seconds), it was found necessary to guide on the planet during the exposure In the eyepiece of the long-focus (61½ feet) guiding telescope two cross wires (spider threads) were inserted. In making the photographs the polar cap of the planet was bisected by these cross-lines, and the telescope held firmly in this position by pressure exerted at the eye-end of the 40-inch. The cross wires are on a perforated strip of sheet brass (with an opening a couple of inches in diameter) that can be shoved back and forth through a slit in the adapter carrying the eyepiece. It is also arranged to move in position angle.

For photographing Jupiter and Saturn, where there is nothing definite to guide on, the intersection of the wires can be made to bisect a satellite, after the image of the planet has been

properly adjusted in the camera. The wires are then held firmly on the satellite, as in the case of the polar cap of Mars

The conditions of seeing necessary for success in this class of work were almost entirely absent during the opposition of Mars. There was only one night, 1909, September 28, on which the conditions were favorable, and this for a short time only The best results are therefore meager, but the promise of success is good when conditions will permit the best work.

The photographs of September 28 show the region of the Syrtis Major. They contain essentially all the details that could be seen with the same telescope visually.

6 Dr MacMillan shows that if two of the masses are finite and equal and revolve about their common center of gravity in circles, and if the third mass is infinitesimal and is projected in the axis of revolution of the two finite bodies then the motion of the infinitesimal body can be determined by means of elliptic functions If the velocity of projection is not too great the motion of the infinitesimal is periodic and it is shown how to construct periodic series representing the motion.

7 Twenty-two photographs were made with the 10½ inch telescope of the University of Minnesota between the years 1897–1910 Ten plates were measured and reduced to standard of October 19, 1909 The faintest stars measured were about fourteenth magnitude. No variability in brightness was detected. The proper motions are all less than $0''.1 \pm 0''.01$ per year The measures have not yet been discussed for parallax.

8 From a study of 3,300 solar prominences, by Dr Slocum, photographed in the light of the H-line of calcium with the Rumford spectroheliograph of the Yerkes Observatory during the past seven years, 1,100 were found which by their shapes or movements indicate a horizontal circulation The tendency is poleward between latitudes 20° and 55°, equatorward beyond 55°, and neutral near the equator The contrast of tendency is greater in the northern hemisphere than in the southern in the ratio of 2 to 1 The average height above the chromosphere of the prominences studied is 0′.7 or 30,000 km The earlier plates do not afford data for determining velocities From the later plates low prominences of the cloud type give apparent velocities from 1 to 10 km per second. One detached cloud at a height of 7′ or 300,000 km shows a horizontal velocity of 50 km per second, while eruptive prominences have been observed the north and south horizontal component of whose velocity reaches 200 km. per second.

9. The paper by Mr. Parkhurst deals with the relative advantages of two proposed systems of standard magnitude stars; those in the neighborhood of the pole, and the white stars in the particular region photographed It compares the possible errors arising from differences of transparency of the sky when a distant region is referred to the polar standards with the errors due to the magnitudes of stars found in the visual catalogues of the region photographed, and the uncertainties due to the allowance made for spectral type of these standards

10 In accordance with experimental demonstrations devised by Dr Siebel, the ellipticity of the earth may be considered as the result in part of the withdrawal of a greater amount of kinetic energy in one of the three directions (in which the molecular motions of a liquid subjected only to its own internal forces may be resolved) during its congelation or solidification. For the experimental demonstration of this phenomenon a drop of water is suspended in a mixture of Beechwood Creosote and ether, which is cooled sufficiently to make the drop of water congeal almost at once The moment when this takes place, the perfect globular shape of the drop changes into an ellipsoidal form, whereby the vertical diameter of the same is reduced at least one fourth, the now solid and flattened drop, on account of the lower density acquired, rises slowly to the surface.

11 A particular kind of dials useful in certain calculations were discussed in the paper by Dr. Wetherill.

12 The present investigation is based on measures of seventeen plates made with the Crossby reflector of the Lick Observatory. It proves impossible to separate the parallax from atmospheric dispersion without further observational material which the Lick Observatory will provide. In addition to masking the effect of parallax the atmospheric dispersion produces shifts of the position of the central star amounting to $0''.2$.

Photographs made with a reflector are probably more subject to the effects of atmospheric dispersion than those made with a refractor.

Certain hitherto unexplained discordances in visual observations of the central star may be due to dispersion.

13. True photographs of the nebula were taken with the slitless spectroscope of the Crossby

reflector of the Lick Observatory Spectrum on the stained plate was compared with spectra on ordinary plates. The spectrum of central star is continuous and like spectra of central star of planetary nebulæ. The spectrum of central star is relatively stronger in ultra-violet light than the bluest of the Orion type of stars The distribution of elements in the nebulous ring are probably not identical.

14 The conclusions reached in the paper by Percival Lowell are That parallaxes beyond 0".067 are too small to be trustworthy, and that the masses of those stars for which alone we have dependable data are, in the mean, almost exactly the same as that of the sun

The following members of Section A were elected as fellows M J Babb, E W Bass H Y Benedict, G D Birkhoff, A B Chace, Arnold Dresden, Eric Doolittle, J C Duncan, T C Esty, Max Fischer, G W Hartwell, H G Keppel, A S Hawkesworth, T H Hildebrandt, N J Lennes, W H Maltbie, Max Mason Helen A Merrill, E J Miles, A B Pierce, A R Schweitzer, F. H. Seares, Mary E Sinclair, Clara E Smith, E R. Smith, A W Stamper, A L Underhill, C E Van Ostrand, F W. Very, W D A Westfall, E J Wilczynski, F B Williams, T W D Worthen, E I Yowell The section elected President E O Lovett member of the council, President C. S Howe member of the sectional committee, and Dean H. T Eddy member of the general committee. On recommendation of the sectional committee Professor E B Frost, director of the Yerkes Observatory, was elected chairman of the section.

G A MILLER,
Secretary of Section A
UNIVERSITY OF ILLINOIS

SOCIETIES AND ACADEMIES

THE BOTANICAL SOCIETY OF WASHINGTON

THE 68th regular meeting of the society was held at the Cosmos Club, Friday, December 16, 1910, at eight o'clock P.M. President W J. Spillman presided. Thirty members were in attendance. H A. Edson, E P. Humbert, F. J Pritchard and W H Long were admitted to membership.

The following papers were read·

Propagation of Sea Island Cotton DR. W. H EVANS

An account was given of the work of the Hawaii Agricultural Experiment Station, with cotton, especial attention being called to the vegetative propagation of the cotton plant At the Hawaii Station experiments with Sea Island and Caravonica cottons have been in progress for several years, and it has been found advantageous to grow them as perennial crops, pruning the plants every year, the Sea Island to about six or eight inches of the previous year's growth and the Caravonica about one half the growth of the season preceding After pruning, the plants start growth rapidly and within five months are producing squares By paying attention to the time of pruning, harvesting can be regulated to some at a time when picking can be most economically done In the experiments described above, the prunings have been taken as cuttings, rooted, and then set into the field In this way a number of superior strains have been propagated without the possibility of crossing As the older plants yield fifty to one hundred cuttings at a pruning and practically all root quickly, this is not as slow a method of propagating as would be at first thought

In addition to increasing cotton by cuttings, it has been found possible to propagate it by budding and grafting, and a considerable number of plants have been successfully top worked with especially fine strains of cotton

Pecan Scab M B WAITE

The pecan, being a native forest tree, is not as subject to destructive outbreaks of fungous diseases as other cultivated nuts and fruits It is native of the Mississippi Valley as far north as Iowa and central Illinois, and extends eastward into Alabama and westward into Texas. It is mainly planted in commercial orchards throughout the cotton belt, but particularly in the district where sugar cane can be cultivated It is not expected, therefore, that the pecan should have such destructive diseases as the bacterial blight of the English walnut, pear-blight of the pear and apple, yellows of the peach tree, or the black rot, downy mildew or phylloxera of the European grape when the latter is grown in the eastern United States

There is an apparent exception to this in the pecan scab, caused by the fungus *Fusicladium effusum* Winter This exception comes about through the transfer of seedlings and horticultural varieties, such as San Saba and Sovereign which originated on the western limit of the pecan in Texas, where the summers are dry, to the humid conditions of the gulf coast states and the Carolinas The Texas group of varieties are

often severely attacked by the scab fungus, particularly on the nuts, and the crop partially or totally destroyed The *Fusicladium* attacks the young leaves as they unfold in the spring The young leaflets and the leaves are successively attacked through the growing season while they are developing Each leaf and leaflet as it reaches maturity becomes immune, or nearly so, to the fungus infections The fungus also attacks the young growing twigs, but particularly the nuts The nuts continue to develop through the summer and remain susceptible until late in September

Infections take place at definite periods, namely, the warm, rainy, humid spells that occur so frequently in the southeastern states An interesting feature was found in relation to the life history of the disease, namely, that a plant louse which becomes common on the pecan in May punctures the epidermis in a regular way along the veins and veinlets The punctures of this plant louse are used as points of entrance by the *Fusicladium*. The fungus can also enter in the direct way and such diseased spots are irregularly located over the leaves, fruit and twigs, but the spots due to aphis infections are arranged in regular lines along the veinlets and far exceed in number all other spots on the leaves The fungus evidently is also assisted in its germination and growth by the honey dew copiously secreted by these aphids

Spraying experiments showed that bordeaux mixture controlled the scab thoroughly and is probably the best fungicide for treating it. Diluted lime sulphur solution also controlled the scab nearly as well and killed the aphids, thus making it a promising mixture to use, at least in part of the treatments The unfortunate fact that the nuts remain susceptible throughout the summer makes treatment difficult and expensive, so that four or five, and even six sprayings may be necessary for success

Extensive observations through the south by a number of pecan students, as well as the experience of practical pecan growers and nurserymen, have shown that a large number of varieties are reasonably resistant to this disease. These varieties have nearly all originated from Louisiana stock or at least from trees grown in the humid regions adjacent to the Mississippi and the gulf. Since many of the finest paper-shell varieties are commercially resistant to the scab fungus, they should, of course, be selected for cultivation in the humid southeastern states Furthermore, instead of recommending the treatment by spraying of the badly scabbing varieties, it is suggested that these varieties, as well as susceptible seedlings, be top-worked to resistant sorts

Bubani's Flora Pyrenæa Dr. E L Greene.

W W Stockberger,
Corresponding Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

The 40th annual meeting (686th regular meeting) was held on December 17, 1910 President Woodward in the chair.

After hearing the reports of the secretaries, the treasurer and the auditing committee, the annual election for the selection of officers for the calendar year 1911 was taken up, and the following officers were duly elected

President—A L Day

Vice-presidents—L A Fischer, C G Abbot, E B Rosa and G K Burgess

Treasurer—L J Briggs

Secretaries—R L Faris and W J Humphreys

General Committee—E Buckingham, W S Eichelberger, E G Fischer, B R Green, R. A Harris, P G Nutting, F A Wolff, W. A DeCaindry and J A Fleming

After the election of officers a buffet luncheon was served

R L Faris,
Secretary

THE AMERICAN CHEMICAL SOCIETY
NORTHEASTERN SECTION

The one hundredth meeting of the section was celebrated by a dinner held at the Exchange Club, Boston, on December 16. President Wilder presided, and there were one hundred members and guests present

The evening was devoted to a consideration of "The Conservation of our Natural Resources" Hon Curtis Guild, Jr, ex-governor of Massachusetts, spoke on the conservation of forests for the sake of both timber and water, and he urged the duty of the federal government to provide national reservations in the east as well as in the west.

Mr H M Wilson, of Pittsburgh, assistant chief of the Bureau of Mines of the Department of Commerce and Labor, described the work of this bureau and dwelt particularly on the progress in the prevention of coal mine disasters and in the care of injured miners

Kenneth L Mark,
Secretary

THE RELATIONS BETWEEN JUPITER AND THE ASTEROIDS[1]

THE story of the smaller bodies which form part of the solar system belongs altogether to the nineteenth and twentieth centuries The discovery of Ceres on the first of January, 1801, followed by those of Pallas, Juno and Vesta, in the next six years, gave promise of a new field for the astronomer Nearly forty years, however, elapsed before any more were found The improvements in star maps about the middle of the century enabled observers to detect new objects more easily, so that from 1845 to 1860 over sixty were captured Since that time scarcely a month but brings one or more to the list, and now nearly 700 are known But this by no means completes the tale New asteroids are constantly being recorded and receive a temporary designation and are perhaps observed two or three times In fact the number of new discoveries has become too great for the few astronomers interested to obtain orbits of sufficient accuracy for future observation It has become a question whether the search should be continued, and if so what plan should be adopted for the computation of the orbits

To the student of celestial mechanics these small bodies furnish many interesting problems The older planets and our own moon have had such thorough attention accorded to the study of their motions, that the outstanding difficulties are almost solely in the last refinements and

[1] Address by the retiring vice president of Section A, American Association for the Advancement of Science, Minneapolis, December 28, 1910.

the most minute consequences of the laws under which they run their courses. Their orbits differ but little from circles, and for practical purposes the series of terms which represent their motions are easily obtained, even if the process of so doing may sometimes be a lengthy one. Far otherwise is it with the asteroids. Many of their orbits are highly eccentric and inclined at large angles to the plane near to which the large planets circulate. But the most interesting problems are those which arise from the near presence of the second largest member of the solar system, Jupiter, whose mass is but little less than one thousandth that of the sun.

Jupiter, great as it is compared with the other planets, is yet small relatively to the central body which mainly controls their movements. In general its average effect on a body which does not come very near to it must be small. Under certain circumstances, it may cause very considerable deviations for a time, even in planets which do not approach it very closely. Astronomers have generally divided the disturbances of the motion of one body produced by another into two classes, periodic and secular. The latter are properly those which change the motion always in the same sense so that they would ultimately cause a change to another type of motion. As a matter of fact, however, the division is arbitrary and in a strict sense inaccurate. So far as we know, all the disturbances produced in our solar system by gravitation are really periodic, but some of the periods are so long, extending to thousands and ten thousands of years, that it is more convenient in the short space of time during which we desire to know the motion to treat certain of them as secular.

These long period deviations are often of very considerable extent. They may be divided into two classes, "proper" and "accidental." In the former all the bodies which have the same type of motion have the long period terms, for instance, the slow oscillations of the eccentricities of all the planets due to the attractions of one on another are of this type and they arise principally because the masses of the planets are small compared with the mass of the sun.

The accidental terms are those arising from a synchronism of periods. They should be regarded perhaps as a result of the defects of our mode of representing the motion in symbolic form. However this may be, their presence causes a real practical difficulty which must be solved. We regard the motion of each body as having a principal period of revolution round the sun in a circle, with deviations from circular motion due to the eccentricity of the orbit, these deviations having periods which are multiples of the principal period. Thus there will always be some period in the motion of one planet very near to a period in the motion of another planet. When the degree of approximation we require is settled there will only be a limited number of accidental corresponding periods. If the difference between the two periods is small, a term of long period arises, and the amplitude of the oscillation is nearly proportional to the long period (or to the period squared) and it might seem that when the period became infinitely great the amplitude would also tend to infinity. In physical terms the motion would be unstable. It is not so in general. When the amplitude begins to approach very large values the motion may still be stable. If it is, one of two things has occurred. Either the difficulty is a symbolic one, that is, our mode of representing the motion is defective for large oscillations, and the difficulty can be bridged by choosing some other analytical

representation, or the type of the oscillation may completely change, when the latter happens, it is generally necessary to change also the symbolic representation

A change in the character of an oscillation which does not cause real instability can be illustrated by a simple example This illustration, while it has no immediate bearing on the question of synchronism, does show the change in the character of the motion which is sometimes produced by a synchronism

Let us consider the motion of a rod, one end of which is pierced to admit a horizontal axle so that the rod can rotate in a vertical plane Suppose that the rod is rotating so rapidly in one direction (called positive) that it makes many complete revolutions in a second There will be slight differences of velocity at various points, differences which can be expressed quite accurately by a single harmonic term Owing to frictional resistances the speed will gradually diminish With diminished velocity the difference between the velocities at the highest and lowest points increases in a ratio which varies very nearly in the inverse ratio of the average speed When the speed has so far decreased that the ratio of the velocity at the top to that at the bottom is very small, we can no longer express the differences of velocity approximately by a single harmonic term, but must include the higher harmonics At the critical stage when the velocity at the top is just zero, the representation fails From our knowledge of the physical side of the problem we know that this failure is not owing to the defects of the representation, but that it is due to a change in the character of the motion The rod ceases to make complete revolutions and begins to oscillate to and fro with diminishing amplitude until it finally comes to rest at the lowest point There is another side to this example which is important for what follows The difference between the velocities at the highest and lowest points is continually increasing, but it does not become infinite. At the critical stage it reaches a maximum value and, becoming discontinuous at this point, has its range suddenly doubled The minima and maxima are nearly equal in magnitude but of opposite signs The range then diminishes until it reaches the limit zero The critical point is, of course, a position of unstable equilibrium and then any small force which may be acting, but which could previously be neglected, may determine the character of the future motion

If we neglect the resistance of the air and imagine that the axle on which the rod is mounted is made to turn in the opposite sense to the original rotation of the rod, the slight friction between the rod and its axle will gradually tend to stop the motion But when the rod is nearly at rest close to its highest position one of two things will happen, either the rod will begin to oscillate as before, or after the first oscillation it will be carried past the highest point and begin to rotate in the same sense as the axle with increasing average velocity.

On the analytical side we have to notice mainly one point Before the critical stage the angular motion is expressed by an angle which increases continuously with the time As the motion gets slower the variations from uniform increase become more and more marked. After the critical stage is passed and the rod is oscillating to and fro, the angle itself varies between two limits which are less than 360° apart, finally settling down to a constant value If, however, the rod begins to make complete revolutions in the opposite direction, the angle diminishes continuously with the time, and its variations from uniformity

become smaller as the mean angular velocity increases negatively It is true that we are accustomed to express the small oscillations of a pendulum by means of angles which increase uniformly with the time, but it is the angle of oscillation which is so expressed and this angle varies between finite limits

I must apologize for insisting at such length on an elementary illustration with which you are all familiar Though it serves to make clear the types of deviations which Jupiter may induce in the motion of an asteroid, the analogy must not be pushed too far It fails to illustrate what may happen to a planet when the stage which corresponds to the rod at rest near the lowest point of the circle has been passed And it takes no account of the numerous short period changes which the planet experiences and which can not be altogether neglected Moreover, forces may be present which may tend to increase the oscillatory motion, so that after a period of hesitation the planet may be compelled to settle down into a motion which corresponds to a rotation of the rod in the negative direction, and this independently of the minute forces which may determine its motion just after the velocity has first become zero

These periodic changes, in which the variable is constrained to remain between finite limits, are generally known as librations The familiar example furnished by the motion of the moon relative to its center of mass is of course a result of the synchronism of its period of rotation about its axis with that about the earth The delicate balancing of the conditions necessary for a libration makes the term unusually appropriate in the cases of the motions of the asteroids

All the earlier discoveries indicated that the smaller members of the solar system, which were not satellites of some planet, occupied a more or less well-defined region between the orbits of Mars and Jupiter But the distribution was by no means continuous It was soon seen that if the mean periods as then determined were arranged in order of magnitude there were gaps in the list which could not be explained by the law of averages It was, I believe, Professor Kirkwood, of Indiana, who first pointed out that these gaps existed at or near the places where the periods are commensurable with the period of Jupiter With the increasing number of planets discovered the discontinuities have become more accentuated In general, the smaller the two whole numbers which represent the ratio, the wider is the gap It has been known that such cases of commensurability produced great difficulties in computation and that the ordinary methods failed The idea was this—near commensurability of a forced period and a natural period produces large deviations, growing larger the more closely the whole number ratio was approached It was thought that when the ratio became exact the deviation would be infinite, or in physical language the orbit was unstable But the deviation, at any rate so far as at present known, does not tend to an infinite limit There appears to be a maximum value which can not be exceeded, and if the planet is so started that this maximum is passed, the ratio of the two periods becomes exact and oscillations about this exact ratio occur The natural period becomes a forced period The analogy to the case of the rod is evident

As early as 1812 Bessel had pointed out that the periods of Jupiter and Pallas are very nearly in the ratio of 7 to 18 and that the attraction of Jupiter must maintain this exactly, that is, the deviations from it would be oscillatory and not secular New-

comb invoked the same idea to combat the opinion that instability was the cause of the gaps in the distribution of the asteroids In a word, the oscillations become librational and have finite limits, or in physical terms, the motion is stable. Thus instead of causing an absence of asteroids at the positions of commensurability, with this idea the action of Jupiter should rather tend to increase the number, since a definite proportion of those very near would be compelled to librate about the exact ratio. It is not clear to what extent the published elements are dependent on the terms of very long periods, but the main issue is not affected, none of the known asteroids in the principal lacunæ appear to librate.

In order that you may see the extent of the inequalities in the distribution I shall throw upon the screen a chart (Fig 1) in which the abscissæ represent the mean periods in days and the ordinates the number of planets with those periods. Each vertical division represents ten days and the number of planets whose periods fall within any division is shown by the height of the curve at that place. There are about 630 asteroids represented. The curve falls to zero at 2,160, 1,850, 1,730 and 1,440 days and there are less well marked minima in other places. Now these four minima include the places where the periods are in the respective ratios of 2:1, 7:3, 5:2, 3:1 to the period of Jupiter. There are also indications of minima at the places where the ratios are 8:3, 7:2, 9:4. These are all the whole number ratios within the range with a denominator less than 5.

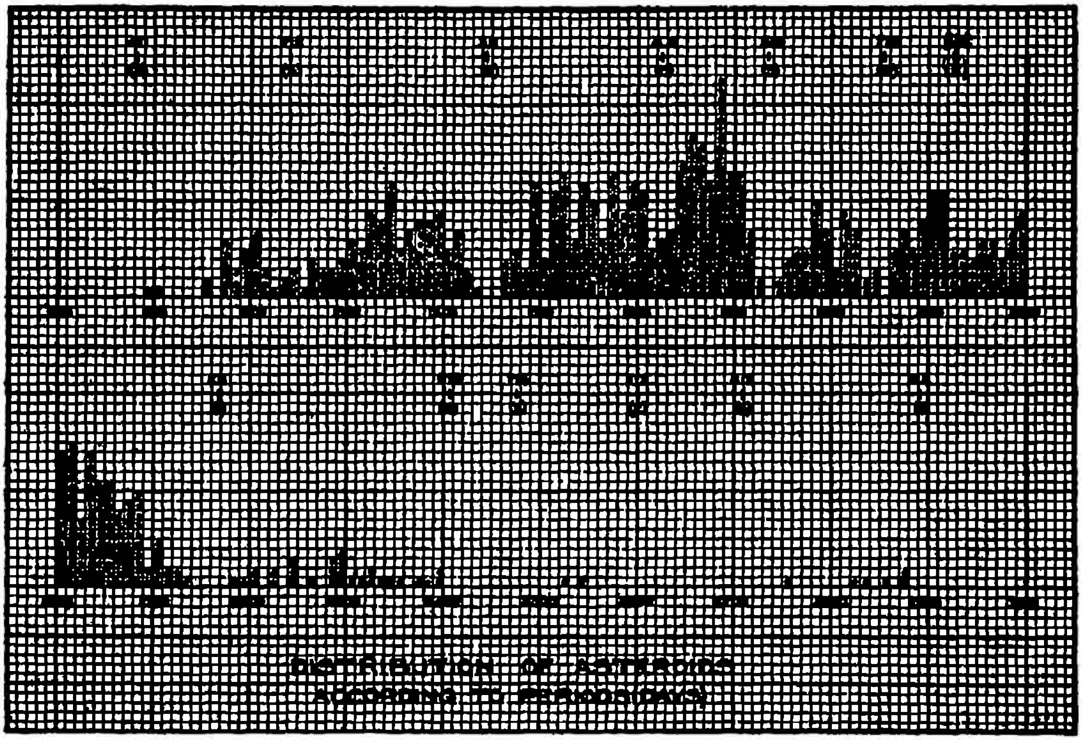

FIG. 1

I am going to speak more particularly

of the gap at the ratio 2·1, this being the most extended of all. Here there are no known planets with periods between 2,120 and 2,204 days; the exact ratio is 2,166, not very far from half way between the two sides of the gap. The comparatively few planets on the outer side of the gap may be a consequence of the general distribution, but the sudden increase in the number on the inner side suggests that other causes have been at work.

In attempting to give an explanation of the phenomena by gravitational forces alone, I must on this occasion omit any mathematical discussion and simply lay before you the main results at which I have arrived. Until this discussion is published in detail, you will naturally reserve your opinions as to the validity of the argument. The reasons for presenting the results in advance of the methods will be evident in the course of my remarks.

The motion of an asteroid near the critical places depends mainly on two quantities, the apparent eccentricity of the planet at any time and the difference between the actual period and the period which is twice that of Jupiter. In the theory both these are quantities such that if at any moment the attraction of Jupiter were suddenly annihilated, the asteroid would continue its motion in an elliptic orbit round the sun with this period and eccentricity. They are thus determined by the position and velocity of the planet at the moment. The attraction of Jupiter causes the temporary period and eccentricity to vary and it is the variations of those two quantities that are the main factors. Now the equations which I have obtained give the principal parts of these two quantities in the form of the square roots of variable functions. In order that they may be real these variable functions must always be positive. One of two things must happen. Either the variability of the functions is forced, that is, it is independent of the motion of the asteroid, or it is free. In the latter case the motion of the asteroid is limited. Under certain general conditions it has long been known that the equation giving the period is to a large extent free so that the asteroid may librate or not, according to the values of the constants entering into the equation, and there is nothing to prevent the constants from having such values. But the period also depends on the eccentricity, and the possible variations of this quantity can not be neglected.

The eccentricity and the difference of the actual period from that of Jupiter are really connected by two equations which can not be independently treated. The eccentricity is also dependent on the short period terms which from this point of view may be considered as of forced period, since the periods of the larger terms are very nearly multiples of the period of Jupiter. I find from this that the eccentricity can not permanently remain below a certain limit and consequently that if a libration of the period about the critical ratio occurs, it can not have a very small amplitude. Referring to the analogy of the rod, we discover the presence of forces which prevent the angle of oscillation of the rod to and fro from descending below a certain finite value. The oscillation can not become infinitely small. This result is in agreement with a theorem proved by Poincaré that no periodic orbit at such a critical place exists.

Reducing to numbers, I find that the lower limit of the slow variation of the eccentricity for an asteroid just before it reaches the critical stage between libration and non-libration is about one twentieth and that at some time it must become as large as one seventh. If there is an asteroid which has passed this stage and is

librating, the upper limit of the eccentricity is at least one fifth. Thus at some time the asteroid must have a comparatively large eccentricity These large changes in the eccentricity take place very slowly Hence the asteroid will during one interval perform many revolutions round the sun in a nearly circular orbit and during another interval many revolutions in a quite eccentric orbit

It has been mentioned that these large variations of the eccentricity are of very long period—the same as that of the libration—and that they increase with the extent of the libration. One may regard the asteroid as slowly extracting energy from Jupiter (or losing it to Jupiter) until it has accumulated (or lost) a maximum amount, when the reverse process takes place Jupiter, owing to its immense mass in comparison with that of the asteroid, will not have its motion sensibly altered by the loss or gain If the type of motion changes when this loss or gain is near a maximum, the asteroid may in future so move that the energy never returns to its original source The type must then be unstable

In my discussion all powers of the eccentricity but the lowest have been neglected. This omission prevents us from obtaining a proper representation of the motion when the eccentricity has risen to so large a value as one fifth, and it is to be remembered that this is the lowest maximum which any librating asteroid can have.

If we take into account higher powers of the eccentricity, it is seen that the extent of the variation must be increased to a considerable extent. I have not so far been able to obtain numerical results beyond this stage. The indications are that the eccentricity increases so much at some time that the stability of this type of motion is threatened and that the asteroid is compelled to take up some other type which is more stable

Although the facts I have stated do not furnish a proof that librations round the ratio 2 1 can not exist, they at least indicate the direction in which stability becomes doubtful. The usual analytical representation, which is possible for moderate librations of the period, fails where the eccentricity becomes very small or great, and the failure is partly due to the short period terms The question which requires solution is whether the failure with large eccentricities is merely a defect of the mode of representation, or whether it is due to actual instability My own impression is that the limits of stability of libration about the principal ratios are so near together, that the chance of an asteroid lying between them is very small This impression is, however, not independent of the observations There are no known asteroids which perform librations round the ratio 2 1 and there are none which approach libration very closely The lacuna in the distribution doubtless admits of other interpretations, but the framing of hypotheses to explain it must properly await a more complete discussion of the consequences of the law of gravitation.

The distribution of the asteroids on either side of the gap furnishes certain tests. The theory indicates that asteroids which initially had large eccentricities are more likely to librate than those with small eccentricities. If the large eccentricities, as I believe, tend to become unstable, it follows that the gap must be wider for them than for the small eccentricities. The next slide (Fig. 2) shows the distribution of eccentricities greater and less than one fifth, round the ratio 2:1. It shows also the distribution by differences of .05 of the eccentricities above .20. The tendency of the asteroids to be more distant from the

gap as the eccentricities increase is very noticeable

Again, according to the theory of a number of asteroids started at various times with the same eccentricity and with periods which bring them near the ratio on the inner side but not such as to allow them to librate, we shall at a future time be more likely to find the values of the eccentricity large at a distance from the gap and small near the gap The reverse would occur with asteroids on the outer side. The observations confirm this result in a marked degree on the inner side The number of known asteroids on the outer side is too small to furnish a test, but if the observed distribution is typical of the real distribution the theory would be confirmed. The need of more asteroids, especially on the outer side, is evident

That these peculiarities are not consequences of the general distribution of the large eccentricities will appear from the next slide (Fig 3) It will be seen that there is a notable deficiency near to the gap and that this deficiency is much more marked than the general distribution would lead one to expect.

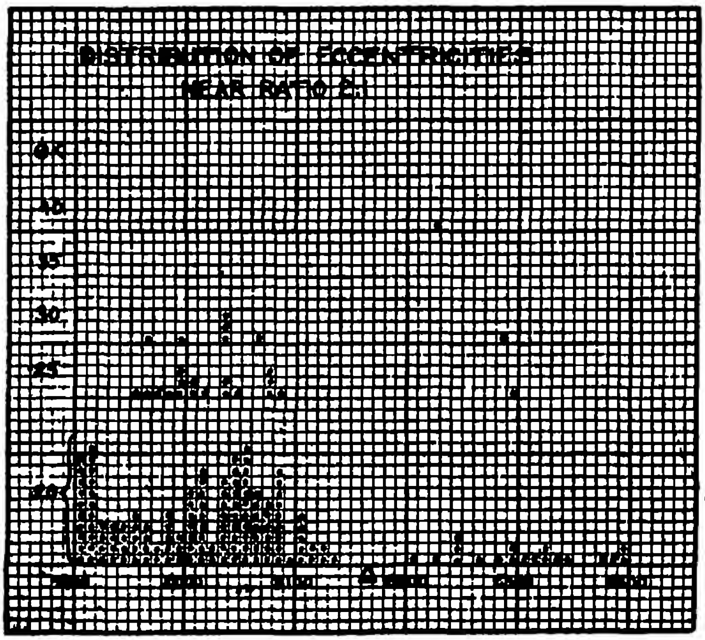

Fig 2

Further support is derived from the inclinations With the ratio 2·1, there should be no very noticeable difference in the distribution of large and small inclinations round this gap, and the next slide (Fig. 4) shows this The curves for i greater than 10° can be compared with those for i less than 10° and also with those for each 5° greater than 10° It is seen at once that there is no selection of the large or small inclinations. The distribution for large inclinations appears to follow the same general law as the distribution for small inclinations. If we refer back for a moment to the slide giving the distribution of the eccentricities, it will be seen how different the two distributions are.

I have hitherto spoken solely of the ratio

2:1. Similar results can be obtained concerning the distribution round the other ratios, but these I must dismiss in a few words, mainly because the details have not yet been worked out It can be stated, however, that the inclination can not in general be neglected when the difference between the two terms of the ratio exceeds unity. Nevertheless, the general result an eccentricity greater than one fifth. This is nowhere more strikingly illustrated than at the values 7 3 and 9:4 There is a large maximum of small eccentricities between these ratios, and only three asteroids with eccentricities so great as twenty-five in the same space A similar phenomenon is observable between the ratios 7 2 and 4 1.

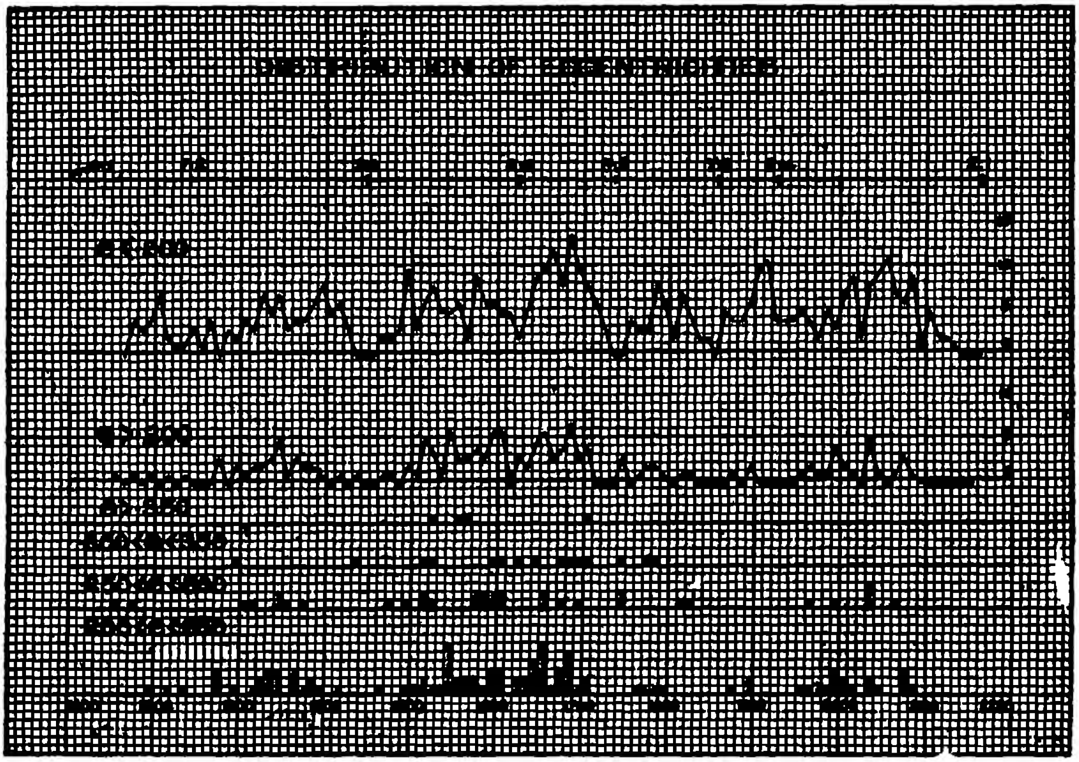

Fig. 3

holds that larger eccentricities are more likely to be absent very close to the gaps than smaller ones.

Referring again to the chart of the general distribution of the eccentricities (Fig. 3), we notice that no one of the ratios, even when the difference of the two terms is 5 (corresponding to a libration with a coefficient depending on the fifth power of the eccentricity), has a close asteroid with

The application of the theory to the satellites and rings of Saturn, though not within the title of my address, can not well be passed over It is now known that the mean periods of the revolutions of Titan and Hyperion round Saturn are exactly in the ratio of 4:3 and that the actual periods librate about this ratio The case is quite similar to that of a ratio 2:1. But here the relative disturbing force is much

smaller and the variations of the eccentricity due to this libration are also much smaller There is, in consequence, less tendency toward instability due to this cause and in fact the numbers do not indicate such a phenomenon The eccentricity does not rise very greatly in value

The divisions of the ring system admit of an explanation if we suppose them to consist of clouds of small bodies subject mainly to the attraction of Saturn and of its satellites A body on or near a critical radius will experience considerable variations of eccentricity which are of long period A narrow ring of these bodies will therefore be moving in ellipses of different eccentricities which vary for the different bodies much more than for bodies not near this ring Hence the range of distance of the bodies composing the narrow ring will be spread out much more than for other rings of the same width. At any given time the number of large eccentricities will on the average be much greater than the number of small eccentricities. On both accounts the number of bodies visible at any one time will be least on the critical radius, rise to a maximum on each side of this radius, and then diminish to the average distribution Thus we get a ring darker than the average between two rings brighter than the average—a result which tends by contrast to increase the apparent difference in illumination

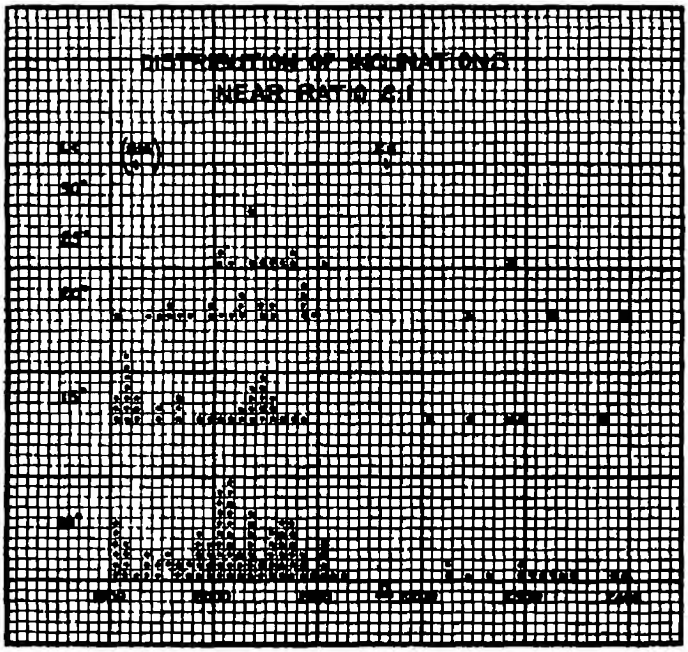

Fig 4

Another result of this variation of eccentricity may be mentioned. Observation shows that the apparent form of the rings is very nearly circular It would seem that the orbits of the separate bodies must have small eccentricities in order to avoid collisions in which the velocities differ considerably. Near a libration region the eccentricities can not remain very small. In the course of long periods of time it would result from this that encounters have taken place which changed the velocities of the

colliding masses sufficiently to cause them to pass away from the region of libration Such collisions may affect the motion in two ways. They may increase the extent of the libration so that the body passes outside of the limits within which librations are possible, or they may at the time diminish the extent of the librations so far that the lower limit of the eccentricity at which librations can be maintained is reached In either case the body escapes from the region of libration and describes an orbit at an altered mean distance and with a period whose difference from the exact ratio never becomes zero Thus while the apparent divisions of the ring are not directly caused by the instability of the librations, they are partly caused by perturbations of large amplitude and perhaps also by the results of collisions arising from those large perturbations.

I have hitherto spoken of the effect of Jupiter's attraction on certain groups of the asteroids A little space must be devoted to the phenomena which are caused in the distribution of the perihelia and nodes of the approximate ellipses in which the asteroids move

When the orbits of but fifty of the asteroids were known it was noticed that the positions of their perihelia tended to group themselves round the perihelion of Jupiter. A similar phenomenon appeared, though not in so marked a degree, with their nodes and the node of Jupiter Newcomb proved that the groupings were consequences of the attraction of Jupiter. His explanation, briefly stated, amounts to this Jupiter causes the perihelia of the asteroids to revolve very slowly round the sun; some of them will librate about the perihelion of Jupiter. In the former case the rates of motion of the lines which join them to the sun are least when these lines are crossing the perihelion of Jupiter, and most rapid when crossing the aphelion of Jupiter Hence at any given time we are likely to observe more asteroids whose perihelia are near that of Jupiter than asteroids whose perihelia are in other positions Asteroids whose perihelia librate must be comparatively few in number. The variations of the eccentricity follow the same law With the nodes and inclinations the effect is less marked In the latest published investigation by von Brunn, who followed Newcomb's methods with 400 bodies, the explanation is confirmed The chart (Fig. 5) which is before you on the screen shows the extent of the variations It is formed with 630 asteroids The points joined by a continuous curve represent the numbers of asteroids whose perihelia lie in the twelve divisions into which the whole circumference has been divided The points joined by a dotted line represent the average eccentricity of those asteroids whose perihelia lie in the corresponding divisions Below are placed the letters *J*, *M*, *E*, *S*, representing the positions of the perihelia, and the letters *J'*, *M'*, *E'*, *S'*, representing the positions of the aphelia of the planets Jupiter, Mars, the earth and Saturn The two upper charts show the results for the first 300 and the last 330 discoveries, and the lower chart the whole 630 The effect of Jupiter is quite clear The traces of the other planets are doubtful. It is true that there is a distinct minimum of the perihelia at the group 10 which contains the aphelia of Saturn and the earth and that it is present in all three charts But there is no corresponding rise at the perihelia, or at any rate the rise is doubtful.

The features of the distribution which are the same in the earlier and later discovered planets can, without much danger of error, be laid aside as consequences of the attractions of the sun and planets.

But there are certain differences which call for special notice. The minima of the perihelia and eccentricity which occurs in the group 7 with the first 300 asteroids occurs in should, of course, be diminished by one eleventh of its height, for strict comparison with the first chart, on account of the total numbers of planets used, but this does not

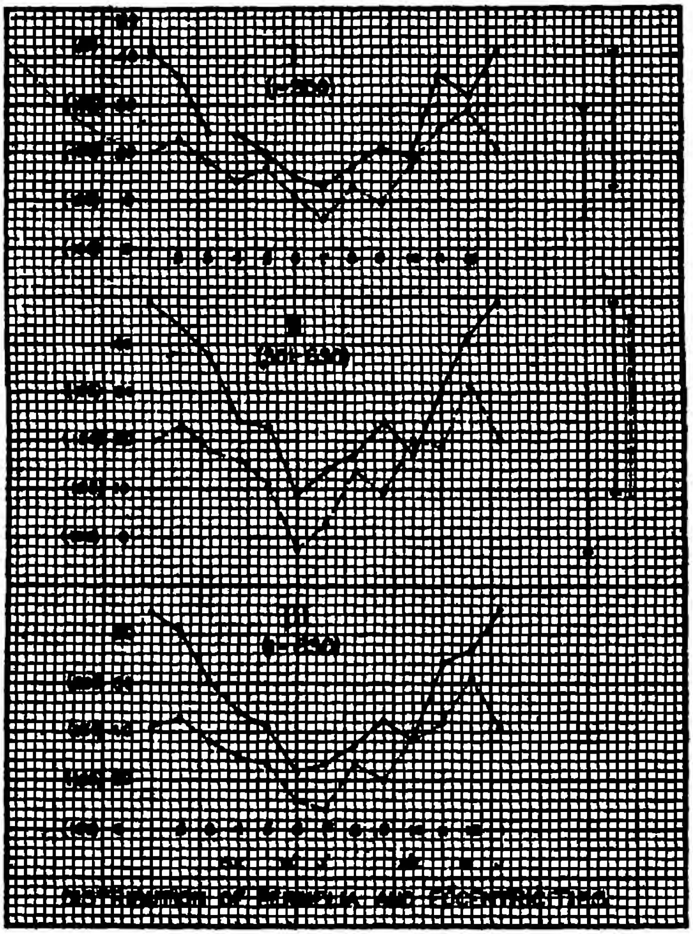

FIG. 5

the group 6 with the last 330 asteroids; the displacement does not appear to be accidental But the most remarkable difference is the greater range between maximum and minimum with the later discovered and presumably smaller bodies with the earlier ones, this difference is observable in both the perihelia and eccentricity curves. Each ordinate of the curve which represents the perihelia in the second chart materially affect the observation The range is greater by nearly 50 per cent. for the perihelia and by nearly 80 per cent. for the eccentricities. Is this a relic of the initial conditions or the effect of some force other than gravitation, for example, light pressure or the impact of material particles entering or leaving the solar system, in which the mass of the asteroids affected will play some part? There is here a wide

field for speculation which I shall not attempt to enter this afternoon.

I have hitherto spoken of asteroids which belong to the main group. Others are scattered either singly or in small groups at quite different distances from the sun Eros, whose orbit lies within that of Mars, is so well known owing to its value for the determination of the parallax of the sun, that it needs only a passing mention. A small group of five asteroids just inside the mean radius at which the period is two thirds that of Jupiter, is of interest as an illustration of the features of those asteroids the large perturbations of which depend on the first power of the eccentricity As at the place where the ratio is 2 1, the planets are on the inner side of the gap It is, of course, not possible to draw any conclusions from so small a number

But the most remarkable illustrations of the problem of three bodies are four small asteroids which have been found within the last five years Before that time the period and therefore the mean distance from the sun of every known asteroid were less than those of Jupiter In February, 1906, Wolf observed a body whose velocity appeared to be unusually small and, in the course of a few observations, it was seen that its orbit could not be very distant from that of Jupiter. Charlier suggested that it might probably be an illustration of one of the two cases in which the problem of three bodies can be solved without approximation. Long ago Laplace proved that if three bodies be placed at the corners of an equilateral triangle and started revolving round their common center of mass with a properly adjusted angular velocity, they would continue to do so indefinitely. The triangle remains equilateral and each body describes an ellipse with the center of mass as a common focus. Further, it has been proved that, provided the masses satisfy certain relations, the motions are stable, that is, small oscillations about the triangular positions would not involve the ultimate loss of the type of motion, the triangle would always remain nearly equilateral As the mass of the asteroid is so small that it may be neglected, the condition for the stability of small deviations is that one mass shall be at least twenty-five times the other, since the sun is over 1,000 times as heavy as Jupiter the condition is well satisfied There seems to be no doubt that the theory is a correct explanation of the facts In the intervening years three more asteroids with similar orbits have been discovered Of the four now known, three are near the point 60° in advance of Jupiter, and one is near the point 60° behind The mean distances of all four from the sun differ but little from that of Jupiter.

If we examine the orbits of these asteroids on the hypothesis mentioned, namely, that they are merely deviations from the triangular solutions, we have to admit at once that the deviations can not be considered very small One of them may move as far as 17° away from the mean position as seen from the sun, and a question naturally arises as to the permanent stability of such large deviations The periods of the oscillations must be very long, not less than 150 years, so that we can not hope to settle the question by direct observation.

These oscillations may be regarded as librational. Bodies well beyond the orbit of Jupiter will revolve around the sun more slowly than that planet, those inside more quickly, and between the two we get a region in which the mean period may be the same. There may then be librations about this mean period which carry the body first inside and then outside the orbit of Jupiter. Referring back to what has

been said concerning the stability of librations around the ratio 2·1, we might be tempted to conclude that the stability of these new asteroids would be still more doubtful This is not so When the mean period is the same as that of Jupiter, the librations are very nearly independent of the eccentricity and inclination unless these are very large, and conversely, the latter are but little dependent on the librations of the mean period It is the only case in which this independence occurs The conditions governing these librations are so different that a separate investigation of them is necessary. I had hoped to lay before you the results which I have so far reached in determining the possible motions of asteroids which circulate with the same mean period as Jupiter In order to do so it would be necessary to exceed greatly the time allotted to me I must content myself with the remark that much larger deviations from the triangular positions appear to be possible and that these may become so extended that a single asteroid may go round both triangular points, passing from one to the other on the opposite side of the sun from Jupiter, and yet not at any time approach very closely to the planet While describing such an orbit the distance of the asteroid from the sun would vary but little

In conclusion, a few words must be said concerning the present condition of the observational material and its future needs. There are about 680 bodies whose orbits are more or less well defined. We have seen that the distribution is by no means uniform With the number on hand we have perhaps sufficient material to determine the general law which governs the arrangement of the orbits This law is, however, only one of the problems which the system presents The student of celestial mechanics needs more asteroids in special regions Reference has been made to the abundance of known orbits on the inner side of the gap which corresponds to twice the period of Jupiter and the lack of material on the outer side Every asteroid added to those very near the gap will be welcome, but there is a real need for more on the outer side In any case new bodies whose periods are close to this ratio should be observed until the eccentricity and inclination can be obtained with moderate accuracy In the course of the search it is possible that one may be found which is within the narrow limits of stability (if the distance between these limits is not zero) of libration At every opposition a few observations of all the known asteroids near the gap should be made, so that the orbits may be verified and the long period terms compared with theory. It will perhaps be advisable to limit the number of asteroids chosen for continuous observation If so, a selection can be made which will give types of small, moderate and large inclinations and eccentricities

A reference to the general chart of distribution of the mean periods will indicate what observational material is needed at the other gaps Aside from the asteroids whose periods have the features which I have just described, every new discovery of a very large eccentricity of inclination should be retained. I would suggest that eccentricities above three tenths or inclinations to the orbit of Jupiter above 20° would perhaps not unduly tax the capacity of those observers who have made and are making valuable additions to our store of knowledge of these bodies.

Finally every asteroid whose period indicates that it is outside the main stream or near its edges should not be lost. More particularly the search might be directed towards the discovery of bodies having the same mean distance as Jupiter, but with

librations more extended than those of the four at present known. As such bodies are moving most slowly when farthest from the triangular points the search would have greater chances of success within twenty-three degrees to thirty-five degrees of Jupiter on either side, or nearly in opposition to Jupiter These three areas are nearest to the earth at different times of the year

Another practical problem is presented by the computation of the orbits This is mainly a matter of expense so far as the ordinary asteroid is concerned, and one way of meeting the difficulty was shown by Watson, who endowed those discovered by himself We need not, however, demand that explorers should be responsible for looking after their own discoveries The asteroids of each type of motion form a group which it would be most economical to treat together if at any time a fund were obtained for the development of the problem. For the present, ephemerides sufficient to identify each body will serve When a reasonable number of accurate observations, extending over a considerable period of time, has been obtained, the comparison of the observations with theory will be of interest to students of celestial mechanics, and the rest of the work will take care of itself

In particular, the Trojan group revolving at the same mean distance as Jupiter and at present consisting of the four bodies, Hector, Achilles, Patroclus and one as yet unnamed, will not suffer from neglect They appear to show one, perhaps the main, stage of transition from bodies superior to the orbit of Jupiter to those inferior to that planet and possibly to those which have become his satellites Their separate paths of motion are interesting to the mathematician, but even more so to the astronomer, since they appear to indicate a new set of periodic orbits in the problem of three bodies The remarkable series of families of such orbits obtained by Sir George Darwin has shown how far such an investigation may lead A single family may have several types Those which I have described appear to belong to perhaps two families at the most, but nevertheless the extent of the work necessary to discuss them is very considerable, and the mathematical portion of it is by no means simple They may be peculiar to systems like our own The work of Sir George Darwin will doubtless have applications to multiple systems of stars, the observational material of which is being rapidly gathered by means of the spectroscope, the heliometer and photographic plate

Theories as to the mode of formation and development of our solar system will, I believe, receive some assistance from these orbits of transition If I have not touched on such questions it is not because the temptation to do so was not present Such matters, however, require an extended discussion under various hypotheses As Brodetski has shown, different hypotheses concerning the nature of possible resisting media lead to quite different results My main object has been to attempt to set forth certain actual and possible types of motion within our solar system at the present time in such a manner as to indicate in what direction the theorist and the observer can best act in cooperation The observer, now that the mass of accumulating material threatens to become too great for permanent record, needs assistance from the theorist so that he may direct his energies into the most useful channels, and not less does the theorist need the help of the observer so that his results may receive confirmation and that he may obtain suggestions for future investigations.

ERNEST W. BROWN

ORGANIC RESPONSE[1]

Recent events in the field of evolution comprehend a number of movements and accomplishments of extraordinary interest. The rediscovery of the facts of alternative inheritance, the formulation of the concepts of equivalent, balanced, paired or differential characters, the results of statistical studies of variability, the analyses of species of various constitution by pedigree cultures, in which the value of fertilization from various sources is carefully measured, the distinction of the biotype or genotype as a hereditary entity, the recognition of the possibilities in the action of pure lines within a specific group, the cytological contributions of fact and forecast upon the physical aspects of heredity, and lastly the presentation of the facts and allowable generalizations identified with the mutation theory, comprise a series of advances, of accretions to knowledge, furnish a broadened foundation for biological science and disclose additional possibilities in all lines of experimental research with living things, besides opening up new realms for speculative thought and stimulating the scientific imagination to renewed fruitfulness

The pressure of undisciplined evidence bearing upon almost all phases of evolution has awakened a freshened chorus of voices crying the virtues of special interests and extolling the sufficiency of theories dignified by age and more or less weighty with authority Those busy with vitalism of various patterns have spun a moiety to mend the breaks in the fragile web of their gossamer tissue made by the impact of new facts Isolation and geographical distribution have again been elaborated to account for all differentiation and what their exponents are pleased to term speciation. The anticipatory formation of structures in a rudimentary condition with a long prefunctional progress, guided by the morphological possibilities and actuated by internal impulses, has again been offered to us, fortified by some facts and much clever logic, in such manner as to avoid most of the serious objections offered, except those of physiological morphology

Natural selection with diverse meanings and manifold implications, has been made to explain development, differentiation and general evolutionary progress, and the tumult is still great about the idea of mutation. Undeniable occurrences of saltatory changes in hereditary lines are numerous and well known, yet it is probable that the importance of mutation as a general procedure varies in different groups of organisms and certain that many shades of opinion as to its exact part in the evolution of living things will always be held

The situation with regard to the theory which predicates direct adjustment of the organism, quickly or slowly, as the case may be, to environic factors, and the full inheritance of the alterations constituting such variations is far more serious The various corollaries of this theory have the force of a certain obviousness, its assumptions have been of ready service to the systematist and biogeographer, and its conclusions have long been tolerated in the absence of decisive tests which are not to be easily made or readily carried out. The time has now arrived, however, when the claimants for Neo-Lamarckianism and all of its conclusions must show cause for its further consideration, or else allow it to drop from the position of being seriously taken as a possible method of evolutionary advance. That no subject is the center of a wider interest is amply demonstrated by

[1] Abstract of presidential address, Society of American Naturalists, Ithaca, New York, December 29, 1910 For full text see *American Naturalist* for January, 1911

the numbers of recent contributions which may be cited. The positive advance implied is so marked as to justify this discussion within two years of the time when the entire matter was presented comprehensively in connection with the various Darwin anniversary programs.

It is unanimously agreed that organisms, plants as well as animals, change individually in aspect, in form and structure of organs, in functionation and habit as they encounter swamps, saline areas, gravelly uplands or slopes, climatic differences identifiable with latitude or elevation, and other physical and biological factors It is assumed that these somatic alterations are accommodative and adaptive, making the organism more suitable for the conditions which produce the changes. Such an assumption is an over-reaching one Any analysis of the changes which an organism undergoes after transportation to a new habitat will disclose one, or a few alterations which might be of advantage in dealing with the newly encountered conditions, but with these are many others, direct, necessitous, atrophic or hypertrophic as to organs which have no relation whatever to usefulness or fitness. Further, a critical examination fails to disclose any theoretical considerations or any actual facts which would connect inevitably the somatic response with the nature of the excitation, outside of the specialized tropisms in which specific reactions are displayed. Even in these the adjustment is of such nature that a mechanism specially responsive to contact, tendrils, for example, responds in the same manner to temperature variations, to which the movements are in no sense accommodations or adjustments.

With regard to the more obvious and direct responses of organisms to altered environment, the records of the operations of the horticulturist, the agriculturist and the breeder as to the behavior of crops, plants and domestic animals, when transferred from one habitat to another, are rich in information. The greater part of such data is the result of observations which do not comply with the ordinary requirements in the avoidance of error so that strict comparisons as to the behavior of organisms under the conditions of various habitats are impossible, but the literature yields many suggestions for experimental research, and the simple generalization that the direct effects of climatic complexes on the seasonal cycle, and upon color, or structural features of the individual, may be repeated or carried over two or three generations, in a habitat where the specific causal combinations are lacking.

Although organized with due regard to the requirements of strict experimentation, the lowland and alpine cultures of plants by Nageli and Bonnier offer us nothing more decisive than the above Likewise many experiments dealing with the responses of organisms to selected agencies have obtained nothing but negative results, even when artificial selection was employed to accentuate or perpetuate the feature constituting the reaction

Buchanan working with *Streptococcus lacticus* finds that phases of fluctuating variations of certain features induced by external exciting agencies may not be fixed and are not transmissible. Jennings' cultures of paramœcia were carried through hundreds of generations with no progressive action in fluctuating variability, while the organism, as a whole, was strongly resistant to all kinds of environic influences: actual alterations were extremely rare. Most of the supposedly acquired characters disappeared in two or three generations by fission.

In the experiments of Sumner mice reared in a warm room were found to differ con-

siderably from those reared in a cold room in the mean length of the tail, foot and ear, and the differences were transmitted to the next generation. The differences may be reasonably designated as being directly individual and somatic, and as having been transmitted by the germ-plasm, which was not subject to the action of various temperatures in the first instance. The reaction forms have an additional claim upon our attention, since they are the ones which distinguish northern and southern races of many animals. The crucial test of the value of the alterations induced in the mice is the one applicable to all of the experimentation on this subject, a test in which two parallel series of cultures, one under the altered environment and the other under usual conditions, should be kept going continuously for a longer series of generations, lots being withdrawn from both, from time to time, for continued comparative culture in normal habitat and under other conditions.

The same considerations apply to Kammerer's experiments with salamanders in which the reproductive habits of *Salamandra atra* and *S. maculosa* were altered to resemble each other by specialized exposure to climatic factors, and while his later work with *Lacerta* has resulted in the production of some extremely striking changes in the color bands which behaved in a Mendelian fashion when paired, yet these have not been followed to the third and fourth generations. The permanency of the induced changes seems highly probable in this case. There is, however, a great body of properly authenticated evidence which demonstrates conclusively that external agencies acting upon bacteria, crustaceans, beetles, fungi and some of the higher types of seed-plants have been seen to result in the appearance of new types or genotypes, which have been found to transmit their characters perfectly through so many generations as to indicate practical permanency.

The names of Beijerinck, Winogradsky, Lepeschkin, Hansen and Barber are associated with records of mutational occurrences in pedigreed strains of yeasts and bacteria under pressure of unusual media or other environic conditions. Some aberrants being propagated by fission and others through the spore stage, some only by selection and others independently. In addition Pringsheim finds many accommodative responses to unusual culture media, temperatures and poisons, which may be cumulated and become fixed in these lower organisms, being transmissible by fission or by spores.

My own earlier work with relation to this subject consisted chiefly of ovarial treatments in which the main and accessory reproductive elements of seed-plants were subjected to the direct action of solutions of various kinds. A new combination of characters constituting a distinct elementary species or genotype was obtained in one plant, and the divergent type has been found to transmit its qualities in the fullest degree, as far as tested, to the fifth generation. Still more marked forms were obtained in a second genus, the divergent progeny being lost in transference to the Desert Laboratory, while distinct responses have been obtained in the extensions of these experiments upon species representing widely different morphological types in Arizona. The greater majority of the tests have been made upon plants growing under natural conditions, so that environmental reaction in addition to that of the specific reagents might be excluded. Progenies representing many species, including thousands of individuals, many of which are divergents, are now under observation. Absolute finality of decision with respect

to the standing of the new types may be reached but slowly.

The important results of Tower, in which new types and various hereditary departures in the Leptinotarsæ were induced by the action of climatic factors on the germ-plasm, have been so fully described and repeatedly cited that any further description is unnecessary at the present time

Gager produced chromosomic irregularities by the exposure of ovaries of *Œnothera* to radium emanations a few years ago and some of the progeny from treated parents were aberrant, but the transmissibility of the new characters was not tested By the use of similar excitations Morgan has recently induced the appearance of white eyes and short wings in the fly, *Drosophila*, which characters seem to be fixed and fully transmissible Both are sex-limited and Mendelize when paired with red eyes and long wings.

Woltereck's cultures of *Daphnia* have yielded some facts of unusual interest in the present connection. The particular group of this crustacean furnishing the experimental material is taken to be very variable, and it was subjected to over-feeding, with the immediate result that the variability of the form of the head appeared to be widened, the size of this structure being increased. This disappeared when lots from the cultures were restored to normal conditions in the earlier stage of the work. After three or four months of over-feeding, the form of the head came within narrower limits, and fewer aberrants were seen, while lots returned to normal conditions, showed a slower restoration of the original form of the head. Two years after the cultures were begun, it was found that the original head form was not displayed by young restored to normal nutrition conditions, the larger helmet being persistent. It seems fairly certain that a new genotype resulted from the long-continued action of the culture medium, which must have influenced the soma and germ-plasm contemporaneously

Klebs, who has long been concerned with the morphogenic reactions of plants, has determined a series of conditions under which stages of mycelial development, asexual, zoospore and sexual or oospore formations in filamentous fungi may be inhibited or variously interchanged Much more important reactions were obtained from *Sempervivum*, the live-forever of the garden In this plant, dense rosettes or propagative bodies are formed at the ends of some branches, and inflorescences were replaced by single flowers by experimental excitation · the number and arrangement of the floral organs as well as of the stamens and carpels could be altered. Furthermore, the deviations in question were found to be transmissible in guarded seed-reproductions

Lastly we now have the fortunate experiences of Zederbauer with *Capsella* which has yielded some conclusions of exceptional importance A genotype of *Capsella bursa pastoris* resembling *taraxacifolium* was found on the lower plains of Asia Minor, and displayed the well-known characters of this form, including broad leaves, whitish flowers, and stems 30–40 cm high. A highway leads to a plateau at an elevation of 2,000 to 2,400 meters, along which the plant has been carried by man, and in this elevated habitat it has taken on certain alpine characters, including elongated roots, xerophytic leaves, stems 2, 5 cm high, reddish flowers, with a noticeable increase of the hairiness of the entire plant. That the distributional history has been correctly apprehended seems entirely confirmed by the fact that when seeds are taken from the lowlands the

alpine characters enumerated are displayed at once as a direct somatic response When seeds are taken from plants on the elevated plateau where their ancestors may have been for many years or many centuries (perhaps as long as 2,000 years) and sowed at Vienna, and at other places, it was found that in four generations the leaves lost their xerophytic forms and structure, but the other characters were retained within the limits of variability The stems showed an increase in average length of 1 to 2 cm, the roots changed as much, but the reproductive branches and floral organs retained their alpine characters The slight modifications undergone by these features were seen to reach a maximum and to decrease in the latest generations cultivated The structural changes and implied functional changes are originally direct somatic responses; there is no escape from the conclusions that the impress of the alpine climate on the soma has been communicated to the germ-plasm in such a manner as to be transmissible, and the suggestion lies near that repeated and continued excitation by climatic factors may have been the essential factor in such fixation.

A related phase of the subject is that of the interposition of environic factors in mutations and hybridizations De Vries appears to have first called attention to the fact that the composition of hybrid progenies of mutants with each other and with the parental form might be altered by nutritive conditions, and the author has described mutants given off by *Œnothera Lamarckiana* in New York which had never been seen in Amsterdam. Furthermore, in discussing the divergent results of De Vries and myself, obtained by crossing the same forms in Amsterdam and New York, the suggestion was made in 1905, that "the manner in which the various qualities in the two parents are grouped in the progeny might be capable of a wide range of variation. Many indications lead to the suggestion that the dominancy and prevalency, latency and recessivity of any character may be more or less influenced by the conditions attendant upon the hybridization, the operative factors might include individual qualities as well as external conditions."

Much more striking evidence upon the matter has been recently obtained by Tower in intercrossing *Leptinotarsa decemlineata, L. multilineata, L. oblongata* and other species in their habitats in southern Mexico, and at the Desert Laboratory. The observations were carried on with both normal and hybrid crosses, in crosses between races which had been built up selectively, and between forms which arose as sports proving conclusively that external agencies may alter the action of paired reproductive elements Kammerer's contribution to this subject consisted in demonstrating that newly induced color characters in *Lacerta* displayed dominances different from those of the original types, while Tennent has proved that the dominances in crosses of *Hipponoe* and *Toxopneustes* variously attributed to seasonal changes, variations in temperature, etc, are in reality to be attributed to the concentration of the OH ions in the sea-water

The first realization of results of importance from cultures widely extended geographically have been obtained in the experiments with Leptinotarsæ by Tower, in which various species of these beetles were studied in their habitats in southern Mexico, in open air and glass houses as far north as Chicago, as far east as the Atlantic and as far west as the Desert Laboratory. Facilities for work upon special problems are now being organized at sev-

eral places and many contributions to the subject may be expected within the next decade.

The plan for work upon the problems of special interest in connection with the Department of Botanical Research of the Carnegie Institution of Washington, implies the establishment of experimental cultures in localities which furnish distinct types of climate or which have characteristic congeries of meteoric factors, as indicated by the vegetation indigenous to them. Secondly, these localities have been chosen with regard to their geographical relations so far as possible, in order that the possible and probable fate of migrating species might be studied. The behavior of plants in these localities is recorded as to anatomical alteration and physiological departure. Having detected some such feature of apparent importance, its reappearance in plants from seeds carried to the original habitat and other locations is followed as one line of evaluation. Contemporaneously, the form is taken into the laboratory and here by analytical experimental tests the effort is made to ascertain to what special agencies the departures are due. Such determination of the identity of exciting agencies has been made by Stockard, who found that the cyclopean embryos of *Fundulus* occurring in nature could be induced by the action of magnesium salts introduced into the sea-water containing the eggs.

Our increased insight into the nature of natural groups of organisms has shown the necessity and suggested the means of observing certain distinctions and precautions in this work. Thus it is of the greatest importance that the living material shall be shown to be either simple genotypes or that its phænotypic nature be apprehended in order that the integration and combination of these forms shall not be mistaken for environic effects. When a lot of plants is taken from one plantation to another, data of the original locality are preserved, as the stand of the plant in that place serves as the control. If the plant is multiplied vegetatively in the test, it might reveal a possible complex character of the material in bud sports, but other divergencies might be well ascribed to local effects. On the other hand, if introduced in the form of seeds, the possible complex character of the material would soon become apparent, especially if the generations were followed properly. In the actual management of the cultures, it is found profitable to reintroduce forms from the original or control lot of various species in order to follow the first stages of their adjustment repeatedly.

The genetic character of environic effects remains to be considered. In any species or genotype there is, withal, a limited number of things included within the morphological possibilities. The appearance of any character in an acclimatization culture raises a question at once as to the standing of the new feature. Is it a regressive character, once displayed by the species and now recalled, or is it to be considered as a character *de novo*, arising simply and directly in response to the external agencies which have been seen to induce it? Thus our general knowledge of the Cactaceæ leads us to assert with some confidence that the reappearance of a full complement of spines in a prickly pear, from which they had all but disappeared, is a regression or return to the condition of the greater majority of the group, a condition which must have been shared by its ancestors at no remote stage in its progressive development.

None of the attempts hitherto made to perfect a theoretical conception which would be useful in interpreting the mech-

anism of environic responses has had anything more than the most limited usefulness. The stimuli of climatic and many other agencies do not imply the introduction of any strange or new substances into the bodies of the organs affected. These agencies might change the dissociations in such manner as to modify the relative number of free ions and thus alter the molecular complex of the living matter in a very important manner however. The intricate play of enzymatic action might also be altered, and any modification of the relative reaction velocities of the more important processes might result in material and permanent change, especially in those cases, in which external agencies interfere directly with the action of the germ-plasm.

The introduction of solutions into ovaries or the exposure of reproductive elements to unusual irradiation may raise the additional liability of disturbed polarity and of modified surface tensions in the cells. It is conceivable that the rearrangement or disturbance of the localizations of substances, especially the mineral salts, might seriously modify the capacities of the bearers of heredity. These direct and material possibilities offer an adequate basis for the organization of experimental research upon the main subject as well as the means of interpretation of results without recourse to schemes of particulate inheritance or theories as to the constitution of germ-plasm to which may be ascribed usefulness in the discussion of other problems in evolution.

The theoretical considerations which might lead us to assign all cases of perpetuation of environic effects to the direct action of the exciting agency upon the germ-plasm are perfectly competent to be questioned with each new bit of evidence brought forward. My own results so far have been all of this kind, as are many of the instances cited, but the case does not appear so simple when, as in *Sempervivum*, somatic alterations are induced late in the ontogeny and are transmitted by seeds borne on the altered branches, and equally serious doubts are raised when one considers the multifold somatic alterations of *Capsella* and the fact that they must be repeated dozens, perhaps hundreds, of times before being transmissible. One must not lose sight of the fact that the soma is itself the most closely interlocking environment of the germ-plasm, and not until the germ-plasm has been exposed to interaction with a changed soma for repeated generations does it undergo the changes necessary to an altered heredity.

The problems of real interest, however, are those which concern the actual influence of environment upon evolutionary development, and with regard to these many generalizations of importance are becoming possible, and their brief summarization may suggest some encouraging advances.

First it is to be seen that not all environic effects induced in the laboratory or by transplantations are heritable, although they may be carried over for two or three generations. No satisfactory basis has yet been found upon which it might be predicted that any effect would be ephemeral or permanent. The characters induced in an hereditary line may be regressive, or awakened latencies or organizations *de novo*. The alterations which become permanent may be cumulative in construction, although they are mutative or abrupt in their appearance in most instances. Abruptly displayed by some organisms, yet they may not become heritable until the germ-plasm has been repeatedly subjected to the direct action of the exciting agency or to the effect of a changed soma for many generations.

Orthogenetic or heterogenetic as to direc-

tion, they may be consequently accommodative or correlational, incidentally adaptive, or wholly inutile in their functional relations

D. T. MACDOUGAL

EDUCATIONAL AND INDUSTRIAL EFFICIENCY

THE latest bulletin of the Carnegie Foundation has many attractive features. The report has evidently been made up in a spirit of good will to education, and any sting that it may contain should be removed by the admirable introduction by Dr. Pritchett. In the course of more than a hundred and thirty large pages the author, Mr. Cooke, makes a number of excellent suggestions, which are none the less excellent because of their lack of novelty. He is aware that the charge of Philistinism might easily be suggested by the tenor of his remarks and he makes some effort to protect himself accordingly. His peculiar point of view seems to give undue prominence to "the cost per student hour," but although we hear much of this phrase in the report we are distinctly told in one place that "It should be borne in mind that the cost per student-hour has absolutely no value in distinguishing relative educational values." If this had been placed as a headline to all the pages, it would have greatly improved the value of the report, and would have been in harmony with this other admirable sentence which might with equal propriety have been inserted as a foot-note to every page: "In the last analysis the usefulness of a university is the measure of its mental, moral and spiritual product—and product interpreted as broadly as you please."

However, although there is much that is excellent in the report, it has many weaknesses. It is written from the point of view of the man who is used to report on the efficiency of a glue factory or soap works. Whenever it touches the strictly educational field and gets away from the factory the trail of the amateur is over it all. It is full of commonplaces, and there is scarcely a question raised that has not been discussed *ad nauseam* by college professors and other officers. It is not lacking in confidence. One marvels at the temerity even of an "efficiency engineer" who can lay down the law so definitely as to how to teach physics, how to conduct a recitation, how to carry on research, when most of us who have devoted our whole lives to such problems are far less confident. There are, however, here and there some pleasing evidences of diffidence. In discussing the important educational problem of janitor service Mr. Cooke says, "A sharp line should be drawn, *probably*, between the cleaning of the buildings and the care of apparatus." The use of the word "probably" is a master-stroke. It conjures up pleasing pictures of janitors handling the delicate instruments of a physical laboratory just as they furbish the brass plates of a glue factory—if indeed "the snap and vigor of the business administrator" which Mr. Cooke admires so much decree that such things are a necessary adjunct to the dignity of the factory. Almost on a par with this use of "probably" is the statement that "There is a good deal of the feeling that lectures to be good must in a way bear the marks of the inspiration of the moment. But a good many men who have the reputation of being high authorities assured me that the carefully thought out plan for a series of lectures would win out every time over the inspiration of the moment idea." Of course they assured Mr. Cooke of this, but they must have smiled at the naiveté of the question and wondered who ever suggested that the presentation of a scientific subject be left "to the inspiration of the moment."

The report shows many evidences of ignorance of the history of education. It suggests as novelties plans that have been tried for centuries and abandoned only after careful consideration. Such, for example, is the suggestion that the rules for the conduct of the students and the punishments for their breach should be put into precise form. The collection of such rules from the archives of the older universities would fill many volumes. Again he says, "It may turn out that ultimately the matter of examinations will be handled by an agency outside of the depart-

ment." This, to his vision, is a far-off divine event to which the whole educational creation is moving If so, it is moving backwards.

Mr Cooke's remarks on the economic use of rooms and buildings are, for the most part, eminently sensible, although he contributes nothing new to the discussion of a very old problem His economic sense is shocked on learning that a lecture room in the department of physics is used only four hours a day, just as it must be shocked when a church is used only a few hours a week, or a life belt only when it is actually needed In some of his criticisms under this heading he seems to forget that colleges have to make the best of the materials that are available and that in many cases an apparently uneconomic use of rooms is forced upon them because their buildings are old, or were designed for other purposes than those to which they have now to be put. He commends one institution for a space-saving device and wonders that it is not adopted in all departments, the fact being that the newer buildings were designed for its use, but the older ones were so constructed that its adoption there would not have been a real economy.

Mr Cooke displays unusual weakness when he takes up the subject of research. Indeed most of what he says on this subject must be received with that mixture of astonishment and embarrassment with which we listen to the words of a distinguished friend who pronounces an absurd judgment on an important subject that he has evidently not mastered Listen to this: "I believe there is a distinct disadvantage to undergraduate students to be near research work I think in the case of physics research workers, their good *influence is more often offset by the introduction into the undergraduate laboratories of the necessarily deliberate and experimental methods of the research laboratory*"!! How unfortunate if "deliberation" and the "experimental method" should contaminate the laboratories—it might detract from the "snap and vigor" of these promising undergraduates. And yet one wonders what possible use there can be in teaching physics at all, if so much care is to be taken to guard the students from catching its spirit and grasping its method. We, in our ignorance, had imagined that the method and the spirit of science were its very essence, especially where undergraduate learning is concerned. We should have accounted any system of education that failed to recognize this as but so much dross and dung (if, at this season, a Scriptural phrase may be permitted) even if it resulted in every undergraduate gaining 100 per cent. in the examinations conducted by Mr. Cooke's "bureau of inspection"

Perhaps enough has been said to indicate that there are serious blemishes in this bulletin. If, however, it be taken for just what it is worth, it can do no harm and may do much good We should regard as a friend every one who helps us to improve our methods and if this report enables us to keep our accounts better, or make a more economical use of our machinery, of course it will be heartily welcomed. The most serious objection that I see to it lies in its abuse rather than its legitimate use I fear that it will tend to increase the administrative machinery of our educational institutions, machinery that is already far too much in evidence. When one listens to all the criticism of our colleges and thinks of the great things that have been accomplished elsewhere with so little machinery and so little noise, one wonders whether it might not be better for us also to settle down to quiet work. Then I confess that all this talk of "cost per student hour" strains my patience to the limit, especially when it is presented under the heading "gauge of efficiency." Mr Cooke frankly recognizes its usefulness to this end, but others may be led astray by the specious analogy with the workings of a factory. A college that had reached the acme of perfection as gauged by Mr. Cooke's standards might be highly inefficient as an instrument of real education. Mr. Cooke tells us that in studying the colleges he has constantly held in mind "the equivalent mechanism" used in the industrial world and apparently he looks forward with pious expectation to the day

when our colleges will run with the uniformity of looms in a mill. Granting with Mr Cooke that there is much that the administrators may learn from the mill manager, it is to be hoped that enlightened public opinion will never permit us to forget that in all matters that are really vital to education there is no "equivalent mechanism" in the industrial world. We are not making shoes or bricks or cloth, but are dealing with material of the utmost complexity and variety, with no two specimens quite the same and no two that need just the same treatment Uniformity in the product is not only unattainable, it is not even desirable, and factory methods are entirely out of place. If we neglect the human factors in our education we are lost and we can not overlook the fact that, without such bulletins as this, there are already plenty of forces at work to give sufficient prominence to mechanical conceptions and mechanical tests. Nor does it require any special effort in this country to stimulate admiration for the "snap and vigor of the business administrator," while the value of snap in the domain of education may very easily be overestimated. Especially am I fearful of its effect on the teacher and the investigator. His path is not too smooth already and even now there are many forces drawing him from the educational sphere where best he can serve society Think for a moment of the effect on men like Newton or Faraday of the "snap and vigor" treatment that Mr. Cooke suggests in his discussion of research. They must make frequent reports on the progress of their research and constantly justify the expenditure thereon. The superintendent of buildings and grounds, or other competent authority, calls upon Mr. Newton.

Supt. Your theory of gravitation is hanging fire unduly The director insists on a finished report, filed in his office by 9 A.M. Monday next; summarized on one page; type-written, and the main points underlined. Also a careful estimate of the cost of the research per student hour.

Newton. But there is one difficulty that has been puzzling me for fourteen years, and I am not quite . . .

Supt. (with snap and vigor) Guess you had better overcome that difficulty by Monday morning or quit

SCIENTIFIC NOTES AND NEWS

AT the recent annual meeting of the American Anthropological Association, held in Providence, R I, officers were elected as follows. *President,* Dr J Walter Fewkes, Washington, D C., *Secretary,* Dr. George Grant MacCurdy, New Haven, Conn , *Treasurer,* Mr. B. T B. Hyde, New York, and *Editor,* Dr John R. Swanton, Washington, D. C.

THE following officers of the American Fern Society were recently elected for 1911: *President,* Dr. Philip Dowell, Port Richmond, N. Y., *Vice-president,* Miss Nellie Mirick, Oneida, N Y; *Treasurer,* Mr. Harold G Rugg, Hanover, N. H; *Secretary,* Mr. L. S. Hopkins, M A, Pittsburgh, Pa.

ON December 20 the Paris Académie de médecine held its annual election, Professor Lannelongue, the vice-president, assuming the presidency and Dr. Gariel, professor of medical physiology at the Paris Medical School, being elected vice-president.

LORD AVEBURY has been elected a corresponding member of the Paris Academy of Sciences, in the section of anatomy and zoology.

THE section of chemistry of the Royal Academy of Science of Stockholm has elected Mme. Curie a foreign member in place of the late Professor Cannizzaro.

MR. ERNST LEITZ has received from the University of Marburg the honorary degree of doctor of philosophy on account of his services to science in having constructed for over fifty years instruments of scientific value.

A 450-acre forest reserve in Vermont has been named the "L. R. Jones State Forest" in recognition of the services of Lewis R. Jones, for twenty years associated with the

University of Vermont as professor of botany, and now professor of plant pathology in the University of Wisconsin.

PROFESSOR C V PIPER, of the U S Department of Agriculture, sailed from San Francisco on January 7 for Manila. He goes to the Philippine Islands primarily to investigate the possibilities of growing hay there suitable for horse feed Before his return he will make extensive investigations of forage crops in India

PROFESSOR CHARLES I CORP, assistant professor of mechanical engineering at the University of Kansas, has gone to the University of Wisconsin to do a year's research work in the hydraulic laboratory.

UNDER the auspices of the Harrison foundation, Dr Arthur Gordon Webster, professor of physics in Clark University, will deliver at the University of Pennsylvania a series of lectures on "Sound in Speech and Music. Its Production, Reproduction, Transmission and Measurement"

PROFESSOR CHARLES E MONROE, of George Washington University, read before the American Philosophical Society, on January 6, a paper on "The Investigation of Explosives at the Pittsburgh Testing Station"

A STATED meeting of the Geographic Society of Chicago was held on January 13, when a lecture was given by Professor Charles K. Leith, of the University of Wisconsin, on the subject "A Summer on Hudson Bay." A reception followed the lecture

DR. FRANCIS GANO BENEDICT, director of the Nutrition Laboratory of the Carnegie Institution, formerly professor of chemistry at Wesleyan University, gave an illustrated lecture on "The Influence of Mental and Muscular Work on Nutritive Processes" before the Middletown Scientific Association on January 10.

ON the evening of January 9, at the Brooklyn Institute of Arts and Sciences, Dr. Edwin F. Northrup, of Princeton University, delivered a lecture entitled, "New Devices for Electrical Measurements." The lecture was illustrated with lantern slides and a collection of instruments for precision measurements in electricity.

AT the fifth annual meeting of the American Society of Biological Chemists held in New Haven, Conn, December 28–30, 1910, the following resolutions were adopted by the society concerning the recent death of Dr Christian A. Herter, one of its charter members:

Resolved, that in the recent death of Dr Christian A Herter, the members of the American Society of Biological Chemists, assembled at New Haven for the annual meeting of the society, desire to express their sorrow at the loss of an eminent colleague and their appreciation of the services rendered by him to the science which the society represents By his own work, by the inspiration, encouragement and support which he so freely gave to others, he rendered inestimable service to the advancement of biological chemistry, and especially in its relation to the problems of practical medicine His kindness of heart and his sympathetic interest in the work of his associates, coupled with modesty regarding his own achievements endeared him to all who came in personal contact with him The spirit which animated his life and which guided his actions in the direction of service to others is expressed in material foundations which he has left for acquiring and diffusing knowledge The same spirit is expressed in the influence he has exerted on the lives of his associates

Resolved, that as a tribute to the memory of our late associate, these resolutions be inscribed on the permanent records of the society and a copy sent to his bereaved family

Committee

THE American Breeders' Association will meet at Columbus, Ohio, from February 1 to 3, under the presidency of secretary James Wilson.

WE learn from the London *Times* that the new "Institut de Paléontologie Humaine," which Prince Albert of Monaco has promised to found in Paris, is to be placed under the patronage of the state. It will be administered by a council of six members, who are to

be of French nationality, and who will be assisted by a committee of French and foreign authorities. The new foundation will be installed in a building of its own which is to be erected in Paris, and in addition to a capital of over $300,000 the institute will be presented with the Monaco collections.

THE five academies of the French Institute held their quarterly plenary sitting on January 5, when the meeting discussed the question of the eligibility of women candidates for the institute The motion in favor of the admission of women, which was prompted by the candidature of Mme Curie for one of the vacant seats in the Academy of Sciences, was rejected by 90 votes to 52 A resolution was adopted in which it was declared that, although the institute did not pretend to dictate to the separate academies, there was an "immutable tradition" against the election of women, which it seemed eminently wise to respect

THERE has been presented to the American Museum of Natural History and placed on exhibition in the Morgan-Tiffany Gem Room a specimen of the new gem Morganite (rose beryl) It is a long oval stone of rich rose color and weighs 57½ carats This gem was named by Dr George F Kunz, the honorary curator of gems of the American Museum, at a meeting of the New York Academy of Sciences on December 3, 1910

ACCORDING to the London *Times* the German Antarctic expedition, under the command of the Bavarian explorer, Lieutenant Filchner, will leave Germany early this year for Buenos Aires, and will proceed from there at the beginning of October *via* South Georgia and the Sandwich Islands to the Weddell Sea The route has been chosen so as to allow of oceanographical research on the way. On arrival in the Weddell Sea it is proposed to establish a base station on the eastern coast as far south as possible, with the necessary equipment for a year's research. A party of ten men will be landed, of whom six—a geologist, a meteorologist, an astronomer, a doctor who is also a biologist, a cook and a sailor—will stay in the station, while the remaining four will undertake a long sledge expedition into the interior of the South Polar continent. Meanwhile the ship will return to the Atlantic Ocean to carry out coastal observations and oceanographical work.

A LETTER from Professor Frost received at the Harvard College Observatory states that Nova Lacertæ was observed at the Yerkes Observatory on December 31, 1910, and January 2 and 3, 1911 An excellent photograph of the spectrum was obtained by Frost with the 40-inch telescope which showed that the spectrum closely resembled that of Nova Aurigæ and Nova Persei, No 2 The position of the Nova for 1911 0 was determined by Professor Barnard as follows· R A. $22^h 32^m 11^s 79$, Dec $+52° 15' 19'' 8$ A star in the exact position of the Nova, of about magnitude 14 0, was found on plates made on August 7, 1907, August 22, 1909, and August 24, 1909 From a photograph made with the 24-inch reflector, Parkhurst and Slocum suspect nebulosity about the Nova, and find the photographic magnitude on January 2 and 3 to be 7 12 and 7 21 Professor Campbell writes that very satisfactory observations of the Nova were obtained at the Lick Observatory on December 31 and January 1 and 2

THE Berlin correspondent of the *Journal* of the American Medical Association writes that on December 10 a mausoleum for Robert Koch was opened in the institute for infectious diseases of which he was director for many years It was formed from some rooms of the institute The funds for the rebuilding, amounting to about $5,000, were contributed by his many pupils and friends The mausoleum consists of two rooms, the first a small antechamber in which some of the scientific instruments used by Koch, his numerous domestic and foreign honorary diplomas, models of the medals awarded to him and other memorials of his life are placed. Here also is the so-called "golden book" of the Robert Koch Foundation for the War on Tuberculosis that contains in an artistic setting the history of the foundation and the autographs of the larger contributors to the fund. In the

special memorial hall, in a niche that is closed with a white marble slab, is placed the urn that contains the ashes of Robert Koch. The walls and floors are all of marble Over the niche for the urn is a marble tablet on which is a portrait of Koch in relief, larger than life size, and on the opposite wall the chief dates of Koch's life are engraved On December 11 the special memorial service took place in the new hall of the university. The large hall which seats about 1,500 persons was filled with a mourning throng which included many physicians, especially members of the Berlin medical faculty, representatives of the government and the chief German medical faculties and representatives of many medical societies as well as of foreign universities and societies. The memorial address was delivered by Professor Gaffky, who was for many years a pupil of Koch and is his successor as director of the institute for infectious diseases.

UNIVERSITY AND EDUCATIONAL NEWS

The report of the tax appraiser on the Kennedy estate has now been published, showing that the bequests for educational and public purposes are even larger than had been anticipated Columbia University receives $2,358,000, New York University $952,000 and Robert College, Constantinople, $1,800,000; the bequests to the New York Public Library and the Metropolitan Museum of Art are in the neighborhood of $2,800,000. Barnard College and Teachers College, Columbia University, each receive $100,000, as do Hamilton College, Elmira College, Amherst College, Williams College, Bowdoin College, Yale University, Tuskegee Institute and the Hampton Institute Lafayette College, Oberlin College, Wellesley College, Berea College and Anatolia (Turkey) each receive $50,000 The bequest to hospitals and to the boards of the Presbyterian Church are very large.

Mr. Carnegie's latest gift of $3,800,000 to the Technical Institute in Pittsburgh is to be used approximately as follows: $2,300,000 for increase of present endowment, $1,375,000 for new buildings, $100,000 for additional equipment and $25,000 on grounds.

The residue of his estate, valued formally at "not more than $50,000," is divided between Yale and the University of Leipzig by the will of Dr. Albert Seesel, a New York physician. With the income there is to be founded at each institution the "Theresa Seesel Fund" in memory of his mother, to be used for researches in biology.

A lectureship on the history and institutions of the United States has been established at Oxford, to be held by American scholars The subject matter of the lectureship is to be the political, institutional, economic or social history or conditions of the United States.

The trustees of the University College of Medicine, Richmond, Va., have awarded contracts for a new college building, to cost $135,000, to replace the one recently burned.

The University of Cincinnati sent as delegates to the meeting of the Ohio College Association and the Ohio Association of Medical Teachers at Columbus during the Christmas vacation, President Dabney, Dean Woolley, of the Medical School, and Professor Jones. President Dabney presented a resolution which was unanimously adopted, asking the Board of Medical Examiners of Ohio and the Ohio Medical Association to join with the Ohio College Association in memorializing the legislature to advance the standard for entrance to the medical colleges in Ohio, by requiring that the entering student shall have done two years of college work, including in this work chemistry, physics, biology (each of these with laboratory courses) and modern languages. The Medical College of the University of Cincinnati has already adopted this standard.

Dr. W. H. Howell has resigned as dean of the Johns Hopkins Medical School, and has been succeeded by Dr. J. Whitridge Williams.

Dr. Josiah H. Penniman, professor of English and formerly dean of the college department of the University of Pennsylvania, has been chosen vice provost

Dr. David L. Edsall, professor of medicine in the University of Pennsylvania, has

accepted a professorship of preventive medicine in Washington University, St Louis.

PROFESSOR GUIGNARD, for fifteen years director of the Paris School of Pharmacy, has resigned his appointment and is succeeded by M. Henry Gautier, professor of mineral chemistry at the school

DISCUSSION AND CORRESPONDENCE

SPECIAL COMMITTEES ON ZOOLOGICAL NOMENCLATURE

TO THE EDITOR OF SCIENCE: The International Commission on Zoological Nomenclature is trying a plan of cooperation with international committees representing the various branches of zoology in an effort to determine in how far it will be possible to reach a unanimous agreement upon the names of the most important zoological genera, together with the type species of the genera in question.

The International Commission of Medical Zoology, established at the Graz Congress, has undertaken a study of over three hundred names applied to the trematodes reported as parasitic in man. This commission is to pass upon the zoological status of the names in respect to synonymy and validity. The report will then be submitted to the International Commission on Nomenclature It is the plan of the latter commission to publish the report, and to invite criticisms upon the same from the zoologists of the world After ample opportunity is given for such criticism it is the plan of the commission on nomenclature to attempt to reach a unanimous ruling upon the names, and to submit this ruling to the next international congress.

The secretary of the international commission on nomenclature is inviting specialists in other groups to conduct similar studies upon the most prominent and best known genera. The plan adopted is for the secretary to select three or more specialists of unquestioned international reputation in a given group, and to request these workers to add to their committee any colleagues whom they may desire. It is hoped that by this means preliminary studies of fundamental and permanent value may be conducted, and that the contending factions, in respect to nomenclature, may be harmoniously united.

The secretary of the commission on nomenclature is adopting the plan of taking man as a center, first working out, so far as may be done unanimously, names to be adopted for the animals most intimately associated with man, and while the undertaking may require years of patient labor, it is hoped eventually to establish a list of not less than ten thousand generic names, agreed upon unanimously, first by the special committee, and then passed upon unanimously by the commission on nomenclature. It is hoped, further, that by this plan an immense number of useless synonyms can be unanimously agreed upon as such, and gradually eliminated from general zoological literature

The scheme naturally depends upon the amount of cooperation on the part of the special committees, which will be formed as rapidly as the work will justify

C. W STILES,
Secretary International Commission on Zoological Nomenclature

FACTS AND PRINCIPLES

TO THE EDITOR OF SCIENCE: May I have space in your columns to reply to the criticism of Professor R. S. Woodworth in your issue of November 25, on my article, "American Educational Defects," which was printed in SCIENCE on October 28, 1910? I have no desire to enter into any needless controversy, but Professor Woodworth seems to me to have misunderstood my language and misconceived my purpose in a way that makes an answer desirable.

There would be little profit in my discussing with Professor Woodworth whether my article is banal or not, which is purely a matter of taste and judgment; but one observation in this connection seems to me pertinent, namely, that there is nothing particularly novel about truth, and that, if educational inefficiency is as prevalent as I have claimed it to be, it would not be strange if it had

been noted repeatedly, nor that there should be general agreement as to its main cause. I should also like to add the explanation that I did not aim to present novel so much as significant truth, and that in writing I bore in mind the maxim of Dr Johnson to the effect that men need to be reminded rather than informed

It would also be idle to discuss the orthodoxy of my method "Orthodoxy," a witty English bishop once explained, "is my doxy, heterodoxy is another man's doxy," and the same definition will serve for what is sound scientific method to-day I did not aim at orthodoxy of method, but at effective presentation of truth in writing; and it seems to me that this is more important than orthodox procedure In my discussion I had to treat a very large subject within very narrow limits, and there is less detail in it than I should wish, but the practical result of my method was to enumerate certain abuses and limitations that I thought I detected in our educational theories and practises, and to explain them as the result of certain economic and temporal conditions the existence of which I indicated Now whatever the theoretical excellence and unquestioned orthodoxy of Professor Woodworth's method, its practical result in his criticism, if he wished to counteract the effect of what I said, should have been to bring forward some reason for believing that the abuses and limitations that I have pointed out do not exist, and that I am either mistaken or malicious when I say that they do. Instead of this, however, its practical result is to use a great many indefinite expressions as if they had an exact significance, and to claim that my case fails unless college presidents and members of governing boards profit directly from the way they administer their trust.

The question of the consistent and accurate use of language is, I know, quite as indeterminate as the two preceding points I have dealt with, for experience has taught me how the mobile and fluid nature of philosophic ideas prevents their being designated and differentiated with entire success by means of language. In an article as compressed as mine, I had to use far fewer checks and elaborations than the character of the ideas demanded, but in spite of this, I do not feel that Professor Woodworth has demonstrated that I have been guilty of any loose or inconsistent use of language I used the word commerce, I think, consistently as "a gigantic business," founded as much on the caprices as on the necessities of men, an activity which is therefore likely to become dominated by "a pursuit of gain" that is more apparent than real which, instead of being an aid to progress, becomes a corrupting influence by creating an indifference to or an unconsciousness of much good that is equally important but less tangible I did not mean to deny the value of commerce, and I did mean to make clear my opinion that, as a guide for human activity, it is an improvement over anything that has directed society in its earlier stages My purpose was simply to show that the absolute control of thought and aspiration by any one activity is bound to create weaknesses that it is the business of education to strive to correct In using the word commerce in the sense I have given, I have used it in accordance with a definition at once more specific and more comprehensive than Professor Woodworth's definitive one; and I have also, I think, laid more emphasis on its vital principle than on its visible exterior, which seems to me a sufficient explanation of what my meaning is when I say (as he predicted I would) that his criticism is an illustration of a very marked tendency to deal with facts and to neglect principles.

SCIENTIFIC BOOKS

The Conservation of Natural Resources in the United States. By CHARLES RICHARD VAN HISE. 8 × 5½ in., pp. xiv + 418, 16 plates. New York, The Macmillan Company. $2.00 net.

As an expert in ores, an authority on geol-

ogy, a leader in education, and a broad student of public affairs, President Van Hise is perhaps better equipped than any one else to treat the natural resources of the country, both in detail and in their relation to the general welfare; and the excellence of his equipment is attested by the completeness and timeliness of his treatise. Conservation of late has become a cult, the influence whereof extends to every section of the country and pervades a large part of our population, yet there is a dearth of data within public reach, partly by reason of the unfortunately limited edition of that three-volume report of the National Conservation Commission containing the fullest inventory ever made of the resources of a nation—and Van Hise's compact book is designed to meet the current condition.

Beginning with a summary history of the conservation movement, the natural sources of national existence are treated in order as mineral resources, water, forests and land, with a general discussion of conservation and mankind. Of the mineral resources the fuels—coal, peat, petroleum and natural gas—are quite properly placed first. Next to America's contribution of a form of government, the most striking fact in the development of the United States is the exploitation of the mineral fuels. This has been done with extraordinary rapidity—virtually within three quarters of a century, chiefly within a generation. The use of mineral fuels not merely made America a manufacturing nation; it multiplied human power over lower nature, and intensified intelligence to a degree revolutionizing the thought of the world. At first idly deemed unlimited in the slack thinking of the time, the use of the abounding natural energy afforded by such fuels so stimulated both industrial and mental growth that new methods arose, especially that quantitative method which forms perhaps the highest expression of human advancement—and as the quantitative method naturally extended to the coals both their limits and the wastes of earlier exploitation were realized and finally measured. The United States contains 60 or 70 per cent of the coal of the world, and is more richly endowed with petroleum and natural gas than any other country; yet the wastes were long greater than the uses, and even yet combustion is so imperfect that only a small fraction (probably less than 10 per cent) of the thermal energy of the coal is actually utilized. But new standards are arising with the spread of the conservation movement, heedless waste is reprobated and is rapidly diminishing, while incomplete utilization is receiving attention, and engineers and inventors are devising means for more complete combustion of the coal and larger application of its energy to the development of power. Paradoxically enough, it would appear that the age of steam opened through the mineral fuels will be closed through better use of the same sources of energy; for coal gasified and used in gas engines averages twice the efficiency of the same coal burned under the steam boiler. America's coal underlies an area of some 500,000 square miles, or 13 per cent of the country, and is estimated to amount to three trillion tons, of late it is mined at the rate of about 450,000,000 tons annually, or say 5 tons per capita for our people, at the current rate of use it would last several thousand years, while at the currently increasing rate (doubling once in seven or eight years) it would be exhausted within 150 years.

Next to coal it was iron that made this country industrially great; the high-grade ores have for a half-century been taken out of the ground and converted into finished product at a rate marking an epoch in world history. When the nation was founded a few pounds of iron sufficed for the average family; now the production exceeds 25,000,000 tons each year, or nearly 700 pounds for each man, woman and child of our entire population. Of high-grade ores we have less than 5,000,000 tons; at the currently increasing rate of mining it would not outlast the middle of the present century—though with proper economy and progressive recourse to low-grade ores the life of the supply will be prolonged at relatively increasing cost.

In no direction is the quantitative method of dealing with resources more novel and helpful than in connection with water—at once a mineral and the menstruum of vitality; and Van Hise applies the method effectively. The average rainfall of the United States is about 30 inches, or only half that required for full productivity of the soil; the aggregate volume is 215,000,000,000,000 cubic feet; or, expressed in terms already familiar throughout the semi-arid region, about 5,000,000,000 acre-feet annually—equivalent to ten Mississippi rivers flowing constantly. Of the total, about one third runs down to the sea in rivers of which many are navigable though little used in aid of commerce—for with the habitual extravagance of the world's wildest wasters our people prefer to pay three or four times the cost of water transportation for carriage of their abounding freight by rail. This is the run-off; and the remaining two thirds (forming the fly-off and the cut-off) are considered with respect to both uses and wastes. Not only are the leading facts well brought out, but the equities arising in connection with this resource are discussed with clearness and conviction. It is growing evident—indeed, it is already recognized by many influential citizens—that in the last analysis the waters of the country belong to the people of the country, and must be administered in their interest, and Van Hise cites and discusses the laws and decisions taking this trend.

Our once abounding but now sadly depleted forests are treated along the lines established by the work of the forest service, *i. e.*, at once as sources of timber, preservers of streams and enhancers of the beauty and habitability of the country as a home for a prosperous and patriotic people; and the extent, uses and wastes of the forest resources are listed and discussed in informing fashion. The lands are treated largely with reference to production—a production measured partly by the soil but yet more largely by the water applied to it naturally or through irrigation. Before the exploitation of the mineral resources and timber began, America was the home of a freehold landed citizenry, and the abounding products of the soil not only easily sustained the food-producing population of the time, but left a large margin for export; but now that a large part of our people are engaged in manufacturing and ancillary industries rather than in producing staples for food and clothing, our exports of these staples are declining—and even at home the pinch of reduced production is felt in advancing prices. It is clearly a need of the time to augment the yield of staples, not merely per acre cultivated, but per worker in the field, it is not only needful to make two ears of grain grow where one grew before, but the farmer must double or triple the product of his own work in order that his manufacturing fellows may be fed; and this may be attained by judicious conservation of the energy residing in fertile soil and intelligent husbandry. For even the teeming population of to-day is not the end for this country, our inhabitants and industrial differentiation are increasing with each generation, and must continue to increase apace if this nation is to fulfill its manifest destiny as the chief home and strength of the Caucasian race. Consistently, Van Hise urges conservation and increase of the elements of fertility in the soil; he indicates and deplores the wastes due to soil erosion and negligent farming; and he applies his own expert knowledge in describing the phosphate deposits of the country and advocating their retention and use. In his closing division he especially emphasizes the current movement as one connected with the public welfare and brings out its patriotic character—for in very fact the perpetuity of this most exuberant and wasteful of nations is at stake.

Throughout, Van Hise crystallizes conservation as a definite and trenchant idea, a specific principle, a basis and guide for action: "Do the principles of conservation demand that it [legislation] shall be done?" (p. 97), "Conservation requires us to encourage concentration and coupling in order that we may get the greatest efficiency of the water" (p. 135); "Conservation does not demand that no tree be cut, but that whenever a

tree is cut, measures shall be enforced which will produce another tree" (p 262)—these are typical expressions.

The book is an outgrowth of a series of twenty lectures, and the arrangement and style reflect the original presentation, there are occasional discontinuities and other minor imperfections which systematic construction in the study would have obviated. In view of that trenchant application of the quantitative method which the conservation movement expresses, it is unfortunate that the indefiniteness of thought and cloak for sharp practise involved in the "long ton" should find expression, still less the rhetorical monstrosity, "short ton", as if there were in well-chosen American terminology any "short" ton—save that delivered by a dishonest dealer. A misleading expression is "reserves," applied to natural supplies—a term unhappily introduced in this country by a foreign student and carelessly adopted through mimetic instinct, there is indeed a "gold reserve," and there have been "forest reserves," but there are unfortunately no coal reserves or iron reserves in the United States—and the very use of the term tends to confuse thought and thereby retard desirable action.

On the whole, despite the few minor blemishes sure to disappear in later editions, Van Hise's book is a highly useful summary of the facts and statement of the principles involved in the conservation movement; and its issue would seem to meet an urgent need.

W J M.

Theoretical Principles of the Methods of Analytical Chemistry Based upon Chemical Reactions. By M. G CHESNEAU Authorized translation by AZARIAH THOMAS LINCOLN, Ph.D. and DAVID HOBART CARNAHAN, Ph.D. New York, the Macmillan Company. 1910. Pp. x + 184 $1 75 net.

The book attempts to show that the phenomena and methods of analytical chemistry can be established on a theoretical basis of thermochemical data and thermodynamic principle, without the use of the electrolytic dissociation theory. In other words, it represents a systematic attempt at practical application of the views held by opponents of the dissociation theory, notably by Professor Kahlenberg

It is divided into seven chapters. The first examines "the influence of the physical state of precipitates upon their purification by washing (size of grains, crystalline state, colloidal state)" The second chapter deals with the principal types of irreversible reactions used in analysis and with the theoretical principles involved The third chapter deals with reversible reactions from the thermodynamic standpoint, carefully avoiding the use of the electrolytic dissociation theory· ionic concentrations are absent from the mass law equations, the molar concentrations being raised to empirical fractional powers (Van't Hoff's coefficient *i*). The fourth chapter introduces the theory of solutions and includes a brief statement of the principal facts upon which the dissociation theory rests. The fifth chapter is devoted to an attempt to show that the dissociation theory can no longer be maintained in science and that it is decidedly overthrown by the work of Kahlenberg. The sixth chapter deals with analytical processes based upon double decomposition of salts Here for the first time the principle of constancy of the solubility product is stated, then an attempt is made to show that it can be dispensed with, not only without loss, but with gain In the last chapter we find, as a substitute for the Ostwald theory of indicators, one based upon "thermochemical data and the hydrolysis of salts in solution" and having "its origin in the principles set forth by Berthelot in his *Thermochimie*" (p. 167). We read here that the change of color of an acid indicator is due to the difference in color between the free acid and its alkaline salt.

On page 127 we read· "If the contradictions between the facts and the theory of ionization appear to require the rejection of the latter, one falls then into another difficulty, that of not explaining the necessity of introducing the coefficient *i* into the general law of equilibrium of Guldberg and Waage." The author thinks, however, that the molecular

association of liquids and its working in the case of salt solutions, together with the hydrolysis idea as set forth by Reychler, fully suffice to explain the chemical peculiarities of salt solutions "... The two parts into which a salt dissolved in water ought necessarily to separate in order to produce a double decomposition, are not hypothetical electrical ions, but a *real* base and acid coming from the chemical action of water upon the salt in solution" (p 133)

It would be of little use to undertake here to defend the dissociation theory Besides, one would mostly have to repeat what was written on various occasions, during the storm and stress period of the theory, by Ostwald's powerful pen Thus, referring to Reychler's hydrolysis idea, Ostwald pointed out in 1893: "Unfortunately, the author has omitted to state how his hypothesis works in the case of salts of insoluble acids or bases, how, for instance, 50 to 80 per cent of zinc hydroxide can remain dissolved, without precipitating out, in a solution of zinc sulphate or zinc chloride"[1] It might also be asked, why a strong solution of common salt, if it contains a great deal of free hydrochloric acid, does not invert ordinary cane sugar, and so forth, and so forth But we will not insist.

The best friends of the dissociation theory have come to feel that it is insufficient, that it needs modification, or rather, perhaps, some addition. But its quantitative triumphs have been remarkable *It will not go unless some new theory is brought forward that will do all that the dissociation theory has done, and more, and that on a quantitative basis, in the way of correlating apparently disconnected phenomena.*

Chesneau's book contains no such new theory, and its blow at the dissociation idea will scarcely be felt. Nevertheless, its contents will be of interest to research students of the theory of solutions. It certainly is well written, well translated by Professors Lincoln and Carnahan, and beautifully published by the Macmillan Company.

"On the Efficacy of Antimony-thioglycollic Acid Compounds in the Treatment of Experimental Trypanosomiasis," by John J. Abel and L. G Rowntree.

"Further Observations on the Immunization of Animals to the Poisons of Fungi," by W. W. Ford.

"Expectorants," by V E. Henderson and A. H Taylor.

SPECIAL ARTICLES

ELLIPTIC INTERFERENCE IN CONNECTION WITH REFLECTING GRATING

In my earlier papers[1] and in a forthcoming theoretical account of the subject, I have shown the practical advantages obtained by associating the interferences of thin plates with the diffractions of the transparent grating—a subject originally suggested to me by the phenomenon of coronas, in which a marked interference phenomenon was also superposed on the diffractions These elliptic fringes may, however, be evoked in other ways than those discussed, and it is to some of these that I venture to refer here

Let the oblique mirror in Michelson's apparatus, for instance, be the usual plate of glass and replace the two opaque mirrors *M* and *N* by identical small reflecting gratings, set at the angle of diffraction of the spectrum, symmetrically to the incident rays Here the elliptic interferences will be seen in the telescope at right angles to the rays issuing from the collimator This adjustment is virtually the same as the plan of returning the diffracted spectra normally to the oblique transparent grating, discussed in the preceding paper in this JOURNAL. The fringes are rings.

Again, in a simple spectrometer adjustment for grating spectra, suppose the grating (either transmitting or reflecting) to be separated into two halves by a division parallel to the ruling. Then on displacing one of the halves, micrometrically, parallel to itself from its original coplanar position, elliptic interference must show itself in a way which is perhaps more direct than any of the methods hitherto treated. The fringes are straight.

THE AMERICAN SOCIETY OF NATURALISTS

The twenty-eighth annual meeting of the American Society of Naturalists was held in the auditorium of the New York State College of Agriculture at Cornell University on December 29 and 30 The eastern branch of the American Society of Zoologists so arranged its program that members were enabled to attend the Naturalists' meeting Many of the members of the Association of Anatomists and American Society of Bacteriologists which were meeting in Ithaca also attended the program Although the Botanical Society of America met elsewhere a number of botanists came instead to the meetings of the Naturalists It may fairly be said, judging from the number present at both sessions, that the Naturalists' symposium was the chief feature of general interest at the entire Ithaca meetings

The one cause of general regret was the unavoidable absence of the president, Dr D T MacDougal, who was ill in the Johns Hopkins Hospital. President MacDougal had so carefully planned the program and had done so much to instill enthusiasm into the entire arrangements that all felt the pronounced success of the occasion to be the result of his efforts

Dr MacDougal's well thought-out and richly suggestive address on "Organic Response" was read at the annual dinner of the society by the vice-president, Professor H S Jennings.

At the meeting of the executive committee and at the business session of the society there was a general expression of the feeling that the present affiliation of the biological societies was highly desirable. The Anatomists, Bacteriologists, Zoologists and Naturalists which met at Ithaca might meet comfortably at many of the universities of the country which are situated, as Cornell is, in a small town It was also felt that there was a far more favorable opportunity for personal discussions and exchange of ideas at a smaller meeting than at a more general one.

The Anatomists, Zoologists and Naturalists had a joint smoker at the Ithaca Hotel on Wednesday evening.

The Naturalists' dinner was given on the following evening at the Ithaca Hotel and was well attended. After the dinner the president's address was read.

The scientific program was given on Thursday afternoon and on Friday both fore- and afternoon.

The central topic of the discussions was the pure line conception in the study of inheritance and evolution Most of the papers in the first part of the program seemed to support the views of Professor Johannsen, while several of the later papers on the program seemed to strongly suggest that selection and a modified Lamarckian view were yet to account for important factors in the

production of new species The valuable feature of the program was the forcible way in which the opposing evidence and ideas of species formation were presented by the several participants. Professor Johannsen, of Copenhagen, who has so strikingly expounded the principles of pure lines and genotypes in the study of inheritance, sent a most suggestive paper to be read before the symposium.

PUBLICATION OF PAPERS

The address of the president and all papers read before the society will appear in series in the forthcoming numbers of *The American Naturalist*

The importance and scope of the papers read are shown by the following titles

H J Webber, Cornell University, "What is a Genotype or Biotype?"

H S Jennings, Johns Hopkins University, "Pure Lines in the Study of Genetics in Lower Organisms"

E. M. East, Bussey Institute, "The Genotype Hypothesis and Hybridization"

W Johannsen, University of Copenhagen, "The Genotype Conception of Heredity"

Geo H Shull, Carnegie Institution, "The Genotypes of Maize"

T H Morgan, Columbia University, "The Application of the Conception of Pure Lines to Sex-limited Inheritance and to Sexual Dimorphism."

J Arthur Harris, Carnegie Institution, "The Biometric Proof of the Pure Line Theory"

R. A Emerson, University of Nebraska, "Some Genetic Correlations in Maize and their Relation to the Formation of New Genotypes through Hybridization"

R. Pearl, Maine Agricultural Experiment Station, "The Inheritance of Fecundity in the Domestic Fowl"

W E Castle, Harvard University, "Are Unit Characters Subject to Modification by Selection?"

F B Sumner, United States Fisheries, "Some Effects of Temperature upon Growing Mice and the Persistence of such Effects in a Subsequent Generation"

J H Gerould, Dartmouth College, "Polymorphism and Inheritance in *Colias Philodice*"

S Hatai, Wistar Institute, "On the Mendelian Ratio and Blended Inheritance."

M F Guyer, University of Cincinnati, "The Nucleus and Cytoplasm in Inheritance"

Many of the papers were followed by interesting discussion, but unfortunately the program proved to be too long to allow full time for this desirable feature.

Several valuable demonstrations were displayed by members of the society

NEW MEMBERS

The following were elected members of the Naturalists J F Abbot, Washington University; R A. Emerson, University of Nebraska; A. W. Gilbert, Cornell University, L. Griggs, Dartmouth College; A Gulick, University of Toronto; J A Harris, Carnegie Institution, S Hatai, Wistar Institute, H. E Jordan, University of Virginia, A. E Lambert, Massachusetts State Normal School, C C. Little, Bussey Institute; H H. Love, Cornell University, S. O Mast, Goucher College; G. T. Moore, Washington University; J. C Phillips, Bussey Institute, R. E. Sheldon, University of Pittsburgh; A. F. Shull, Columbia University; W J. Spillman, U. S. Department of Agriculture, H. B. Torrey, University of California, G. Wagner, University of Wisconsin, H J. Webber, Cornell University; E. N. Wentworth, Iowa State College, D D Whitney, Wesleyan University

The following officers were elected for 1911:

President—Professor H. S. Jennings, Johns Hopkins University

Vice-president and Chairman of Eastern Branch—Dr Geo H. Shull, Carnegie Institution.

Treasurer—Professor E. M East, Bussey Institute.

Secretary—Professor C. R Stockard, Cornell University Medical School

Additional Members of Executive Committee—Professor W L Tower, University of Chicago, and Dr B. M Davis, Cambridge, Mass.

CHAS R. STOCKARD,
Secretary

THE AMERICAN CHEMICAL SOCIETY

THE forty-third general meeting of the American Chemical Society, held at Minneapolis, December 28–31, was attended by 275 members and guests and, like all recent meetings of the society, was simply an echo of the general enthusiasm that pervades its membership.

Owing to the fact that over 175 papers were presented, it was necessary to hold meetings of all of the divisions and the meetings of the Division of Agricultural and Food Chemistry, Division of Fertilizer Chemistry, Division of Pharmaceutical Chemistry, Division of Industrial Chemists and Chemical Engineers, Division of Physical and Inorganic Chemistry and Division of Organic Chemistry, were well attended.

A point especially worthy of note was the

successor of the Biological Section under the chairmanship of Dr Carl L Alsberg, of Washington, D. C. Forty four papers were presented before this section of a strictly chemical nature bearing upon biochemical problems

The meeting of the Section of Chemical Education, held at a time when all the industrial chemists could meet with them, proved decidedly interesting and the discussion was general.

On the first day of the meeting the chemists all gathered in general session to listen to eight general addresses as follows

"The Lost Arts of Chemistry," W D. Richardson

"The Basis of Industrial Efficiency," A D Little.

"Synthetic Metals from Non metallic Elements," Herbert N McCoy

"Progress in Food Chemistry," H E Barnard

"Mechanism of Cell Activity," Carl L Alsberg.

"Waste Wood and some of its By products," Geo. B. Frankforter

"The Formation of Carbohydrates in the Vegetable Kingdom," Wm McPherson

"The Efficiency of the College Graduate in the Chemical Industry," Chas F Burgess

The address of the retiring president, Wilder D Bancroft on "A Universal Law," was an exposition of the general application of the theorem of Le Chatelier to all kinds of natural phenomena as well as those of a chemical nature

Possibly the complimentary smoker in the rooms of the Commercial Club was as thoroughly enjoyed as any one feature of the meeting for an unusually witty program had been arranged and original songs bearing upon individual chemists and chemical phenomena were thoroughly enjoyed; also the mementoes furnished to the visiting chemists were pleasing to all This, however, was not the only social function of the meeting, for several receptions and teas were arranged for the ladies and the banquet on Friday night, which was attended by some two hundred members, was also graced by their presence

Excursions to the following places and works were taken by the members Russell Miller Milling Co, Pillsbury Flour Mills Co, Washburn-Crosby Co, Consolidated Milling Co, Minnesota Linseed Oil and Paint Co, Archer-Daniels Co, Midland Linseed Oil Co, St Anthony Falls Water Power Co, Cream of Wheat Co and International Stock Food Co.

On Saturday afternoon a large number were treated to a sight seeing trip covering both the cities of Minneapolis and St Paul A number of the chemists also had the privilege of viewing the wonderful paintings of La Farge in the state capitol of Minnesota

The announcement of the election of Alexander Smith as president of the society and of Louis Kahlenberg, Frank K Cameron, Geo B Frankforter and E C Franklin and E G Love as councilors at large met with hearty approval and applause

M C Whitaker was elected editor of the *Journal of Industrial and Engineering Chemistry*, and the report of a committee recommending a decided broadening of the policy of that journal was adopted

The secretary announced a net gain of 550 members for the year the society now having a membership of over 5,100

CHARLES L PARSONS,
Secretary

THE TWENTY-THIRD ANNUAL MEETING OF THE AMERICAN PHYSIOLOGICAL SOCIETY, NEW HAVEN, CONN., DECEMBER 27–30, 1910

For the first time in many years the physiologists of the country, together with the biochemists and the pharmacologists, met apart, not only from the American Association for the Advancement of Science, but also from the group of societies associated with the naturalists Sixty three of the society's one hundred and seventy-five members were present The meeting was successful in point of attendance as well as in the number of communications of high merit and in able discussions An important factor in the success of the meeting was the splendid arrangements made for us by the local committee (the biologists of the Sheffield Scientific School, the Yale Medical School and the Connecticut Agricultural Experiment Station) and the cordial hospitality extended by this committee to the visiting members

The following papers and demonstrations were presented and discussed during the six scientific sessions (two of these being joint sessions with the biological chemists)

E B Meigs, "The Osmotic Properties of Smooth Muscle"

Gertrude F Barbour and P E Stiles, "Localized Activity in Skeletal Muscle"

C J Wiggers, "Pulse Pressure Variations in the Pulmonary Circuit"

G W Fitz, "A Preliminary Report of Work

with the Shadow Pupillometer in Determining the Constants of Pupillary Reactions"

G H Parker, "The Olfactory Sense in Fishes"

F C Becht and A B Luckhardt, "On the Source of the Immune Bodies in the Lymphs"

J R Murlin and J R Greer, "The Heart Action in Relation to the Respiratory Metabolism"

W B Cannon and C W Lelb, "The Receptive Relaxations of the Stomach"

S Simpson, "Are the Parathyroids Capable of Replacing the Thyroids Physiologically?"

L Loeb, "The Function of the Corpus Luteum"

T B. Osborne and L B Mendel, "Feeding Experiments with Mixtures of Isolated Food Substances"

Elizabeth Cooke and S P Beebe, "Autolysis of Liver as Affected by Thyroid Administration"

J Loeb, "Further Experiments on the Antagonistic Action of Salts"

O Schreiner and M X Sullivan, "Biological Analogies in Soil Oxidation"

S J Meltzer, "The Migration of Solutions in Animal Bodies Deprived of their Cardiac Circulation"

G N Stewart, "Measurement of the Blood Flow in Man"

W H Howell, "The Action of Pure Thrombin"

G W Fitz, "A Shadow Pupillometer for the Accurate Study of Pupillary Reactions"

S Simpson, "A Modification of Schäfer's Frog-heart Plethysmograph"

Y Henderson, "A Quantitative Pneumograph"

E D Jackson, "An Automatic Shellacking Device"

A J Carlson, "The Mechanisms of Automaticity, Coordination and Conduction in the *Limulus* Heart" (Demonstration)

A B McCallum, "Some Illustrations in Animal and Vegetable Cells of the Gibbs-Thomson Law of Surface Condensation of Solutes"

H Cushing, E Goetsch and C Jacobson, "The Hypophysis and its Relation to Carbohydrate Tolerance"

H C Jackson, "Changes in the Blood and Tissues following Double Nephrectomy and Urethral Ligation"

J Auer, "The Causation of Acute Anaphylactic Death in the Rabbit"

J R Murlin and L. H. Mills, "The Influence on Metabolism of Oils given Subcutaneously and Intravenously"

A B Luckhardt and F C Becht, "The Relation of the Spleen to the Fixation of Antigens and the Production of Immune Bodies"

P A Grant, Elanor Van Alstyne and S. P. Beebe, "The Absorption of Protein through the Intact Intestinal Epithelium"

F Wills and P B Hawk, "The Stimulation of the Gastric Secretion under the Influence of Water-drinking with Meals"

V E Henderson, "The Effect of Temperature upon the Heart"

J S Miller, D D Lewis and S A Matthews, "The Effects of the Intravenous Injection of Extracts of the Different Parts of the Hypophysis"

W B Cannon, "Observations on the Nature of Gastric Peristalsis"

F H Pike, "The Mechanism of the Asphyxial Rise of Blood Pressure in the Spinal Animal"

J. A E Eyster, "The Effects of the Intravenous Injection of Extracts of the Pineal Body"

D R Joseph and S J Meltzer, "Inhibition of the Duodenum Coincident with the Movements of the Pyloric Part of the Stomach"

A J Carlson, J. R Rooks and J R. McKie, "Attempts to Produce Experimental Hyperthyroidism in Different Animal Groups" (with demonstrations)

Owing to the absence of the authors the following papers were read by title only.

W Koch and C C Todd, "The Nature of the Chemical Combinations of Potassium in the Tissues."

A Hunter and M H Givens, "The Allantoin and Purin Metabolism in the Monkey"

T G Brodie, "The Gaseous Metabolism of the Heart"

G Lusk, "A Method of Removing the Glycogen in the Human Subject"

P B Hawk, "The Activity of the Pancreas during Moderate and Copious Water Drinking with Meals"

W M Hattrem and P B Hawk, "On the Intestinal Putrefaction during Copious and Moderate Water drinking with Meals."

Clara Jacobson, "On the Mechanisms of Inhibition of the Parathyroid Tetany in Mammals by Calcium Salts"

W Jones, "A Specific Nuclease for Guanylic Acid"

The society appropriated $100 to the *American Journal of Physiology* towards defraying the cost of the index volume

The following new members were elected:

Harvard University J H Pratt, W. J. V. Osterhout, A Forbes

University of California T B Robertson, S. S Maxwell

Washington University W E Garrey, D E Jackson.

University of Pittsburgh C Brooks, R E. Sheldon.

Cornell University J R Greer, E Sachs, J F. McClendon.

Columbia University W G MacCallum

Western Reserve University D Marine

Yale University L L Woodruff

The following officers were elected for the year 1911:

President—S J Meltzer

Secretary—A J Carlson.

Treasurer—W. B Cannon

Members of the Council—J Erlanger, F S Lee

A J CARLSON,
Secretary

UNIVERSITY OF CHICAGO

THE AMERICAN MATHEMATICAL SOCIETY

The seventeenth annual meeting of the American Mathematical Society was held at Columbia University on Wednesday and Thursday, December 28–29, 1910, extending through the usual morning and afternoon sessions on each day Sixty-two members were in attendance President Maxime Bôcher took the chair at the opening session, yielding it to Professor Kasner, Ex-president Osgood, and at the morning session on Thursday to the president-elect, Professor H B Fine The council announced the election of the following persons to membership in the society Professor Percy Hodge, Columbia University; Mr C G P Kuschke, University of California, Professor Marion B White, University of Kansas Eight applications for membership in the society were received

On Wednesday evening thirty of the members gathered at the annual dinner, which has for many years been a pleasant adjunct to the regular sessions

It was decided to hold the summer meeting of the society at Vassar College in 1911, and at the University of Pennsylvania in 1912 A committee, consisting of Professors H. S White, P F Smith and the secretary, was appointed to make the necessary arrangements for the summer meeting of 1911

At the annual election, which concluded on Thursday morning, the following officers and other members of the council were chosen

President—Professor H B Fine.

Vice-presidents—Professors G A Bliss and W. R. Berry

Secretary—Professor F N. Cole

Treasurer—Professor J H Tanner

Librarian—Professor D E Smith

Committee of Publication—Professors F N Cole, E W Brown and Virgil Snyder

Members of the Council (to serve until December, 1913)—Professors H F Blichfeldt, J L Coolidge, C J Keyser and J W Young

The total membership of the society is now 642, including 60 life members, an increase of 24 during the past year The total attendance at all meetings of the year was 317, the number of papers presented was 145, 202 votes were cast at the annual election The treasurer's report shows a balance of $8,124 53, a slight increase over last year, although the university subventions for the *Transactions*, amounting to $500 per annum, have been discontinued and the society has paid an installment of 1,000 francs of its contribution toward the publication of the works of Euler The income from sales of the society's publications during the year was $1,660 21 The life-membership fund now amounts to $3,901 83 The library shows the normal increase, the total number of books on the shelves being now 3,508

During the past sixteen years the society has expended for printing the *Bulletin*, *Transactions* and other publications $42,473 57 The total returns from publications have been in the same period $15,375 20 The stock of publications on hand may be fairly valued at about $10,000 The university subventions have amounted to $8,100 Editorial and administrative expenses during the sixteen years have been $11,739 14 The society is about to undertake the publication of the Princeton Colloquium Lectures and the republication of Klein's Evanston Lectures

The following papers were read at the annual meeting

S Chapman "A note on the theory of summable integrals"

H. H Mitchell "Concerning a rotation group in six-space"

Virgil Snyder "An application of a (1–2) quaternary correspondence"

A S Hawkesworth "Three new dimension theorems"

W R Longley "Singular points on the discriminant locus of an ordinary differential equation"

R G D Richardson "Theorems of oscillation for two self adjoint linear differential equations of the second order with two parameters"

Maxime Bôcher "A simple proof of a funda

mental theorem in the theory of integral equations"

J L Coolidge "The metrical aspect of the line sphere transformation"

E J Miles "The absolute minimum of a definite integral in a special field"

J C Fields "A method of proving certain theorems relating to rational functions which are adjoint to the fundamental algebraic equation for a given value of the independent variable"

F F Decker "On the order of a restricted system of equations"

Paul Saurel 'On the classification of crystals"

A B Coble "An application of Moore's cross ratio group to the solution of the sextic equation"

A B Coble "The cubic surface and plane six point"

C L E Moore "Conjugate directions on a hypersurface in S_4 and some allied curves"

W H Bates "An application of symbolic methods to the treatment of mean curvature in hyperspace"

H B Phillips "The Galois theory of sets of multipartite variables"

J R Conner "Correspondences associated with the rational plane quintic curve"

L P Eisenhart "Conjugate systems and envelopes of spheres"

Joseph Lipke "Natural families of curves in a general curved space of n dimensions"

O E Glenn "On the discriminants of ternary forms"

Professor Bates's paper will appear in full in the January *Transactions* Abstracts of the other papers will be included in the secretary's report in the March number of the *Bulletin*

The Chicago Section of the society held its twenty eighth regular meeting at the University of Chicago, December 28–30 The next meeting of the society will be held at Columbia University on Saturday, February 25

F N Cole,
Secretary

THE SOUTHERN SOCIETY FOR PHILOSOPHY AND PSYCHOLOGY

The sixth annual meeting of the Southern Society for Philosophy and Psychology was held at Chattanooga, Tenn, December 27 and 28, 1910 The meetings were presided over by Professor Edward Franklin Buchner, who delivered the presidential address on the topic "Learning and Forgetting"

The following papers and reports [illegible]

Thomas P Bailey, New York Bu[illegible]nicipal Research, "Some supposed [illegible]encies of the American Negro A [illegible] Psychological Study of the Race Prob[illegible]"

Jasper C Barnes, Maryville Co[illegible], "[illegible] Pressure Curve in Voluntary Control"

Knight Dunlap, Johns Hopkins Uni[illegible], "A Study in Rhythm Perception"

David Spence Hill, Peabody College [illegible]ers, (*a*) "Some Needs for Child Wel[illegible] South," (*b*) "Class and Practise Ex[illegible]," (*c*) "A Comparative Study of Children[illegible]"

A J McKelway, secretary, Natio[illegible] Labor Committee for the Southern Stat[illegible] Labor in its Relation to Education"

R M Ogden, University of Tenn[illegible], (*a*) "The Order of the Days of the Wee[illegible] Pythagorean Philosophy," (*b*) "Kno[illegible] Expressing"

Jno Pickett Turner, Vanderbilt U[illegible], 'Locke's Place in the History of Thoug[illegible]"

Tom A Williams, Washington, D C, [illegible]) "[illegible] Modern Interpretation of Dreams and [illegible], Sleeping and Waking," (*b*) "Intellec[illegible] cocity The Rôle of the Inclinations and[illegible]ity A Comparison of the Principles and [illegible] employed for educating John Stuart [illegible] Boris Sidis's Son"

The officers elected for the year 1[illegible]: *President*—Dr Shepherd Ivory Franz[illegible]ment Hospital for the Insane, *Vice p*[illegible]— Professor A Caswell Ellis, University [illegible] *Secretary treasurer*—Professor R M[illegible], University of Tennessee

Vacancies in the council were filled [illegible]tute that body as follows for a three y[illegible], Professors E F Buchner, Johns Hop[illegible]versity, and W B Smith, Tulane U[illegible]; for a two year term, Professor Bruce [illegible], University of Virginia, and Presiden[illegible] Pearce, Breneau College, for a one-y[illegible], Professors David Spence Hill, Peabody [illegible] for Teachers, and W C Ruediger, Geor[illegible]ington University

It was voted to hold the next meeti[illegible] society at Washington, D C, in affilia[illegible] the American Association for the Adva[illegible] Science, provided the American Psychol[illegible] Philosophical Associations meet at the [illegible] and time

THE METHOD OF SCIENCE[1]

SCIENCE governs human life by determining the conditions of existence and by furnishing the means of civilization. Religion prescribes the motives, government formulates the customs of mankind, science fixes what we can do and how. If, at the present meeting, we appropriately emphasize the rôle of science, it does not imply that we belittle the ethical or social factors of civilized life, but answers the demand for a more just and general recognition of the actual importance of pure science.

We are so accustomed to the practical advantages that have followed from abstruse science, that we connect them with their source only by a distinct mental effort. The wonders of practical science have been recited so often, that their reiteration has become tedious, and we no longer feel strongly impelled to felicitate mankind on the parlor match, the telephone and the antitoxines, although we indulge at present in an unsubdued excited anticipation of wonders to come, especially in the domain of medicine. Are we not all on the watch for the announcement of the cure for cancer, and vaguely for other new and astounding reliefs from disease! Such concentration of interest upon novel practical results is not wholly favorable to science.

It is true that a large amount of investi-

[1] Vice-presidential address delivered before the Section of Physiology and Experimental Medicine of the American Association for the Advancement of Science, at Minneapolis, December 29, 1910.

gation is going on which aims to secure immediate practical results. In chemistry and medicine especially the activity in the work of applied science is very great. This condition gives a powerful fresh reason for defending pure abstruse science. Applied science always has been, is now, and probably always will be distinctly subsidiary to pure science The final justification of all scientific research is undoubtedly the power it creates for the use of mankind, but the power must be created before it can be used A little study of the history of science should suffice to convince any reasonable mind that the command we possess to-day over nature is due to the labors of men, who have almost invariably pursued knowledge with a pure devotion uncontaminated by any worship of usefulness These devoted idealists have gathered the varied mighty harvests by which all men have profited, but the debt of gratitude to them is unpaid.

The pursuit of abstruse science needs to be encouraged. It is insufficiently esteemed This doctrine ought to be emphasized on all suitable occasions, but especially before the section of experimental medicine The people cry for relief from sickness and their demand for prompt useful discoveries is so urgent that there is danger in it, since it tempts medical investigators away from the fundamental enquiries, which, answered, will give great results, and seduces them to work exclusively at secondary problems, from the solution of which quicker, but smaller results may be expected. Pure science is broad, it embraces all. Applied science is a congery of fragments, of isolated problems, which lack cohesion and are without any necessary connection with one another. It is easy to understand why students of applied science have seldom made great discoveries.

In fact, scientific knowledge will not be compelled We have to take what knowledge we can get, and by no means can we get always what knowledge we want Pure science adapts its undertakings to these rigid conditions, and works where the opportunity is best—not so applied science.

Let us recall a few of the epoch-making discoveries When Galileo turned his [illegible] face up towards the swinging lamp in the Cathedral of Pisa and as he looked discovered the law of the moving pendulum, he was in quest of pure knowledge We can not conceive such a man actuated by any lower motive. Even when we learn of his astonishing the Venetian merchants by enabling them to see their far-off vessels through his newly invented telescope, do we not feel that it was merely an episode to Galileo? Such a man does not ask, "What use is it?" His demand for knowledge was insatiable. When Newton thought out the problem of gravity and his theory of planetary motion; when Malpighi explored the structure of animals with his crude microscope; when Lavoisier created modern chemistry; when Cuvier combined comparative anatomy and paleontology and made the combination yield new revelations; when Lyell proved geological history to be an evolution and not a succession of cataclysms; when von Baer against immense difficulties traced the development of the chick; when Schwann demonstrated the correspondence of cellular structure in animals with that of plants—was one of them actuated primarily by the wish to get practical results? We have only to read their works to convince ourselves that they were all in search of knowledge for knowledge's sake. Yet they are the giants of human history, who in importance are approached by few monarchs or statesmen. Compared with the growth of science the shiftings of govern-

ments are minor events. Until it is clearly realized that the gravest crime of the French revolution was not the execution of the king, but the execution of Lavoisier, there is no right measure of values, for Lavoisier was one of the three or four greatest men France has produced.

Since pure science has been preeminent in the past not only in furnishing useful knowledge, but also as a chief foundation of human progress, and is likely to long continue equally preeminent, it is well worth while to study the general principles by which original research is guided. No previous definite study of these principles is known to me, although I have searched not a little to find one. All that I have been able to discover are treatises on logic, the reading of which, most active investigators would, I fear, find tedious and unprofitable rather than helpful and inspiring. We have too many real difficulties to quite enjoy wading through the artificial morass of pedantries, in which logicians by profession embed their significant truths. The stricture is severe, but not too severe even for so sound and valuable a work as Jevons's "Principles of Science." It must be doubted very seriously whether the study of logic is really essential for the right training of an investigator. While it goes without saying that logical thinking is indispensable in science, neither may it be overlooked that thinking is a complicated physiological function, which is brought to efficiency by practise, and that training by actual use is the one indispensable means of disciplining and developing the function. Playing the violin is a complicated physiological function, but it is not thought necessary that the violinist should study the anatomy of the muscles and nerves of the hand and arm. He perfects himself by practise. Anatomical knowledge might enable him to understand why he can make certain motions and can not make others. Our analogy limps perhaps, but is a real analogy, for practise in right thinking creates the necessary habit of being logical, and ability to describe the mental processes in the language of logicians is an accomplishment which few even of the greater scientific discoverers possess.

It is my belief that the logical work of scientific men is usually well done, and is the part of their work which is least faulty. The difficulties and the majority of failures are due, it seems to me, to two chief causes, the first inadequate determination of the premises, the second exaggerated confidence in the conclusions. If I am right, the method of science is the result of the effort to get rid of these two causes of error.

We must recognize in starting that the expression "the method of science" means more than "logic," being far more comprehensive when rightly defined. We can not alter the fundamental conditions of knowledge, for we are still unable to add new senses or improve the brain—although eugenics dreams of a future with such possibilities—nor can we change the nature of the phenomena. The same fundamental resources are available for daily life and for science. We must be clear in our minds on this point, in order to comprehend that the fundamental distinction of the scientific method is its accuracy. As I have said on another occasion "there is nothing to distinguish the scientific method from the methods of every-day life except its precision. It is not a difference in kind or quality, but a quantitative difference, which marks the work of the true scientist and gives its validity." Such being the case, a broad examination of the method of science reduces itself to the

study of the general principles of securing accuracy

If you will examine frankly your own opinions and those of your acquaintance you will, it may be presumed, quickly acknowledge that many, perhaps most, of the opinions are not of scientific accuracy. On the contrary, they are, to a large extent, mental habits and the result of the summation and averaging of impressions. I, for example, know a generous man, but can give very little of the evidence on which my opinion is based. I know a seacoast on which fog occurs in summer quite frequently, yet I can not state how often the fog occurs nor just when I have observed it. At sundry times I have received an impression, in one case of the man's generosity, in the other of fog. The exact data can not be recalled, but the impression on my mind has been fixed by repetition. The evidence is lost, but the conclusions persist and are accepted by me as correct. For my practical needs they are sufficient. We get along in ordinary life satisfactorily enough with opinions thus formed by summation. Most human opinions, even when they are merely imitative, originate in this way, and are correspondingly unreliable. If we seek to explain the fallibility of ordinary opinions and testimony must we not attribute it to the absence of the detailed evidence and the consequent impossibility of verifying the testimony?

We are thus led to recognize the preservation of the evidence as the fundamental characteristic of scientific work, by which it differs radically from the practise of ordinary life. I venture accordingly to define the method of science as the art of making durable trustworthy records of natural phenomena. The definition may seem at first narrow and insufficient, but I hope to convince you that it is so comprehensive as to be not only adequate, but also almost complete.

All science is constructed out of the personal knowledge of individual men. Science is merely the collated record of what single individuals have discovered. Accordingly, we must consider, first, the way in which the individual knowledges are recorded and collated. The process begins, of course, with the publications of the special scientific memoir in which the investigator records his original observations and makes known his conclusions. Permit me to quote from Oldenburg's preface to the first volume of the *Philosophical Transactions of the Royal Society*. The date is 1665.

> Whereas there is nothing more necessary for promoting the improvements of Philosophical Matters, than the communicating to such, as apply their Studies and Endeavours that way, such things as are discovered or put in practice by others; it is therefore thought fit to employ the *Press*, as the most proper way to gratifie those, whose engagement in such Studies, and delight in the advancement of Learning and profitable Discoveries, doth entitle them to the knowledge of what this Kingdom, or other parts of the World, do, from time to time, afford as well of the progress of the Studies, Labours and attempts of the Curious and Learned in things of this kind, as of their compleat Discoveries and performances.

All that he says is true to-day, although our taste has changed in favor of shorter sentences.

It is interesting to note that our present standards for original memoirs have developed gradually. In Harvey's essay on the circulation of the blood, published in 1628, there are no precise data as to his observations. The author does not think it necessary to specify how he has laid bare the heart or how often he has repeated his observations. His descriptions of the beating heart are vividly realistic. He writes with conviction and authority. The reader

is compelled to believe him Harvey, however, does not provide information to facilitate repetition of his work—he offers little aid towards the verification of his results Francesco Redi, the founder of experimental biology, published his "Generation of Insects" in 1660 His experiments proved that insects are not spontaneously generated in putrifying meat. His conclusion[3] is sound, but he does not give more than a general account of the actual experiments A century later Spallanzani established the modern standard, and in his works we find the details as to his evidence put down with scrupulous care, for example in his paper on the circulation (1773) the single experiments are exactly described But Spallanzani in this, as in other respects, was far in advance of his time.

In a cotemporary article we expect a presentation of all the data necessary to render subsequent verification by other observers possible We further expect clear information as to the amount of material on which the observations were made, or the number of experiments on which the work is based In other words, a modern investigator will hardly receive consideration for his researches unless he furnishes every aid he can to facilitate criticizing and testing his results This severe standard has been only gradually evolved, but is now stringently enforced in all departments of science and is the response in our practise to our need of eliminating the purely personal factor It would be advantageous if scientific authors generally viewed the obligation of providing for verification as an even more serious duty than it is esteemed at present. It might, indeed, be a wholesome practise to demand that every scientific article should contain a special section or paragraph on the means of verifying the result, for verification by *Fachgenossen* is second in importance only to discovery in the progress of science

The conditions of scientific progress have changed greatly though very gradually. Two hundred years ago the number of active investigators was small This year there are at least ten thousand men of substantial ability carrying on original researches, consequently each theme is being worked at by several men, and the final outcome is the consequence of collaboration, which is none the less actual and effectual because it is unorganized, and is usually not formally designated as collaboration For example, our present knowledge of the complex and very varied processes of cell-division has been constructed not merely by successive accumulations, but also by incessant debate and repeated mutual criticism. If we examine a paper on mitosis we find not merely the author's own observations, but also references to other related investigations, to specify which there is often a formidable bibliography Within a generation the modern science of bacteriology has been created. Within a few years radiology, the wonders of which still thrill us, has suddenly come into existence Both great achievements are the results of both the original observations and also the constant mutual discussions of a number of scientific men

These conditions have rendered great men somewhat less important than formerly. Science grows by the accretion of ideas. Now, a great man has, let us say, twelve new ideas, where a man of ability has one. If science gets twelve new ideas it matters little whether they come from one man or from twelve. To a certain

[3] At vero ubi loco ita clauso illud (stercorem bovis) dentinui, ut intrare muscae & culices, et ova sua ponere non possent, nihil omnino natum vidi.

extent numbers make a substitute for genius—but nothing probably will ever replace that type of great genius, to which we owe most, the man who has a great thought, which no one has ever conceived before

The nineteenth century in response to the new conditions, which have arisen in its course, has added another new standard for scientific memoirs—they must include a conscientious consideration of recent and cotemporary related work Now the second step in science-making, after recording the new original observations, so as to make them accessible to others, is the collation of these same observations into broad general results The aim is to eliminate the personal factor and to impart the character of impersonal absolute validity to the conclusions

In addition to the original memoirs science profits by a large number of publications, almost all of which are of modern, often of very recent, creation. Broadly speaking, their aim is to promote that collation, which is begun in the original memoirs Germany is the home of most of these undertakings, which are familiar to us under the names of "Jahresberichte," "Centralblatter" and "Ergebnisse" So far as I have learned, Jacob Berzelius's "Jahresberichte" for the physical sciences, which Gmelin translated into German, issuing the first volume at Tübingen in 1822, was the first ancestor, the Adam, of this modern biblic race, which therefore can not yet celebrate its first centenary As concerns those branches of biology known as the medical sciences, the summarizing publications under consideration have become important only since 1870, although they began earlier. For biology 1834 may be taken as the starting point, for it was the initial year of Schmidt's "Jahrbucher der gesammten Medicin" and of Johannes Müller's first Jahresbericht Meckel had just died and Muller assumed the editorship of the *Archiv für Anatomie und Physiologie,* which he conducted for so long that it is still often known simply as Muller's *Archiv,* although the *Archiv* since his death has had several distinguished editors Müller wrote for the *Archiv* the first Jahresbericht entirely himself His report is interlarded with many keen criticisms and even with references to unpublished observations of his own Later he engaged others to assist in the yearly reports, which were kept up until 1857 Their place was taken by Henle's Jahresberichte, which were continued until 1871, when they in turn were replaced by the *Jahresberichte der Anatomie und Physiologie* founded by Franz Hoffmann and Gustav Schwalbe in 1872. The growth of anatomical science is indicated by the fact that in round numbers 400 pages sufficed for the abstracts of anatomical papers in 1872, but 1,500 were necessary in 1908 Similar increases have occurred in the output of the other medical sciences, hence it has become more and more difficult to bring out the Jahresberichte promptly—a delay of two or three years is common To meet this growing difficulty the various Centralblatter have been started—those with which we are here concerned are periodicals issuing small numbers (Hefte) at short intervals and filled with brief abstracts of recently published researches.[3] They have proved of limited utility and their completed volumes are so inconvenient to consult that one

[3] The dates when some of the Centralblätter started are as follows für medizinische Wissenschaften, 1863; für Physiologie, 1887; für Bakteriologie, 1887; für allgemeine Pathologie, 1890; für allgemeine Biologie, 1910 Although the number of German "Centralblätter" is very large, yet in other countries corresponding magazines are viewed with limited favor.

habitually avoids them. They are useful, perhaps, at the moment of publication, but the back volumes encumber rather than enrich our libraries. Fortunately the last decade of the nineteenth century brought us a new and very valuable form of report, the avowed purpose of which is the systematic collation of results. I refer to the "Ergebnisse." The earliest of them known to me was founded in 1892 by Merkel and Bonnet to cover anatomy and embryology. The annual volumes contain essays on various topics which really collate recent discoveries, they differ fundamentally and advantageously in method from the Jahresberichte and Centralblatter, by presenting a combined picture rather than abstracts of single papers. They are substantial contributions to science because they systematize and coordinate the new information. The enterprise of Merkel and Bonnet deserves our most grateful appreciation. Its value is witnessed to by the foundation of similar "Ergebnisse" for other sciences. The series for pathology began in 1896, for physiology in 1902, for zoology in 1909. In the admirable *Revue d'Histologie* (1906) they found a French follower. The "Ergebnisse" are likely to prove of increasing importance and as the number of new investigations mounts higher and higher their comprehensive essays will become even more indispensable than at present.

Although logically more remote from the original sources than the annual and special collations just reviewed, yet handbooks are historically older. Formerly one man could master completely his whole science and keep up with all the new discoveries. In 1834 Johannes Muller wrote the whole annual report upon anatomy, comparative anatomy and physiology, and did it well. A hundred years ago a single author could write a thorough manual. To-day such a feat is impossible. The difficulty has been met with commendable success by cooperation. A science is divided into chapters, each chapter is undertaken by a specialist, and so the task is done, but with consequences easily anticipated, for every one of us knows some of these huge modern composite hand-books.

We recognize in the present methods of recording and collating scientific discoveries many adaptations which are due, it seems to me, essentially to the mere increase in the number of workers. But though the methods are modified the essential steps are the same: *first,* the record of the individual personal knowledge, *second,* the conversion of the personal knowledge by verification and collation into valid impersonal knowledge, *third,* the systematic coordination and condensation of the conclusions.

A defect—perhaps the most serious defect of our education—arises from our failure to make our students appreciate vividly the fundamental fact that science is based on personal knowledge. Our students are allowed to graduate from college, for the most part without any comprehension of this great truth. The best of them start forth with a high reverence for the library, the place of records, but quite unaware that a still higher reverence is due to those who, by being the first to observe unknown things, have founded the knowledge, the records of which the library keeps.

The divergence between philosophy and science shows itself most conspicuously in the personal mental attitude, which philosophy cherishes and science seeks to overcome. Philosophers still discuss philosophers and their systems, scientific men pursue impersonal knowledge with such

ardor that they are apt to know little of the history of science

May I venture to divert your attention to two matters, which suggest themselves in connection with our main theme? The first is the question of style in original scientific articles, for we probably all are ready to admit that the care bestowed on the presentation in print and picture of original discoveries is often insufficient. Do we not all know articles which are bungled in form and weakened by prolixity? Surely the heads of laboratories should insist by example and precept that all the workers under their influence should write clearly and briefly—for if an author fails to show respect for his own scientific work, how can he expect others to respect it? Yet there are few matters so important as intensifying the world's respect for science For us, whose language is English, the standard should be the highest Rivarol in his famous prize essay said "ce que n'est pas clair, n'est pas Français"—but we might say what is not true, is not English By its wealth of synonyms and its logical construction the English language is preeminently adapted to the exact statement of scientific truth. We should not misuse so fine an instrument, which if well employed is sure to win for Anglo-Saxon science the wide influence it deserves Good thinking is the blastema of good style, therefore our learning will never appear good if our learned articles are written badly

The second matter for digression is a suggestion concerning bibliography. Almost every important memoir is accompanied by a bibliography. Custom prescribes it The literature is indicated by the titles in full, and when the list is well made the volume, page and plates are all given Other memoirs on the same subject give similar bibliographies We know from experience that these selected bibliographies are very helpful to those who follow—but is there not a needless waste through frequent repetition? There would be a great economy if we had a complete international catalogue of the scientific literature of each year, in which all the publications of each author were entered with serial numbers It would then suffice to quote an author's name, the year and the serial number, as, for example "John Doe, 1910, 1," to give a complete reference, for it is to be presumed that the catalogue would be found in at least all the principal scientific centers of the world This system has been utilized privately already, and experience with it has demonstrated its eminent practicability and simplicity in use The International Catalogue of the Royal Society, which is at present not only imperfect but excessively inconvenient and really of little use, might be transformed by the plan suggested into an invaluable aid to science The plan could be still more easily applied to the cards of the Concilium Bibliographicum of Zurich It is deplorable that the Royal Society neither cooperates with, nor adopts the system of, the Concilium As matters are the International Catalogue remains merely a respectable failure

To return The records, which we have considered thus far are those which serve to make the discoveries of individuals available for others As soon as the discoveries are properly collated and sufficiently verified they become permanent parts of science Many definitions of science have been given, and did time permit it might be profitable to quote some of them—but is it not sufficient to define science as *knowledge which has acquired impersonal validity?*

We must now attempt a general examination of the records, which are used pri-

marily to help the original investigator, though often preserved to assist his successors. The simplest form of record is the preservation of the actual specimen. Scientific museums are essentially storehouses for such records. Most of them to be sure maintain public exhibitions, which interest, stimulate and possibly instruct the public, but the precious part of their collections comprises the objects possessed, which have served for some original discovery. Scientific museums are very modern, nearly all those in America have been started within a few years. The Philadelphia Academy of Natural Sciences was founded in 1812, the Boston Society of Natural History in 1831, Agassiz's Museum in 1859, the National Museum in Washington in 1876,[4] and the Field Columbian Museum in 1893. A history of museums, dealing especially with the progress of the art of caring for collections would be cheering to read, for it would picture a remarkable growth of the appreciation of the value of objects as original records. This may be illustrated by the change of opinion as to "type" specimens of plants and animals. The systematic zoologists and botanists constantly lament that the earlier authors did not preserve the actual specimens from which they described new species and they consider no pains too great to ensure the preservation of "types" of new species, which any cotemporary worker describes. In the Laboratory of Comparative Anatomy at Harvard we have felt the influence of the example of museums and have established a permanent embryological research collection, a sign of the times and an acknowledgment of the new insistence upon the preservation of the original proofs of discoveries.

[4] The genesis of this museum dates back to Smithson's bequest, 1826, and was in part due to accumulations of materials from various government expeditions before 1876.

The progress of science is marked by the advance in the art of making research records. We all admit, in other words, that the progress of science depends partly on the perfecting of old methods, but chiefly on the invention of new ones. Despite the enormous variety in their nature and aims, all our technical methods have this in common that their real purpose is to yield us records. Our microscopes, spectroscopes, measuring instruments and many another apparatus have indeed their primary scope in rendering possible observations, which are impossible with our unaided senses. They enlarge our field of enquiry and put precision within our reach. Yet their usefulness is conditioned upon their enabling us to make records which else would remain beyond our power. On the other hand, there is a still larger class of apparatus which are obviously designed to make records. What has been said concerning apparatus might be repeated concerning methods.

It is remarkable that the vast majority of methods and apparatus are contrived to furnish a visible result. Sight has long been acknowledged by science as the supreme sense. Perhaps the philosopher was right who asserted that nothing is really known until it is presented in a visible form. We biologists can not deplore too frequently or too emphatically the great mathematical delusion by which men often of very great, if limited, ability have been misled into becoming advocates of an erroneous conception of accuracy. Although I have expressed myself on the subject before its importance justifies recurring to it. The delusion is that no science is accurate until its results can be expressed mathematically. The error comes from the assumption that mathematics can express complex relations. Unfortunately, mathematics have a very limited scope and are

based upon a few extremely rudimentary experiences, which we make as very little children and of which probably no adult has any recollection The fact that from this basis men of genius have evolved wonderful methods of dealing with numerical relations should not blind us to another fact, namely, that the observational basis of mathematics is, psychologically speaking, very minute compared with the observational basis of even a single minor branch of biology Moreover, mathematics can at the utmost deal with only a very few factors and can not give any comprehensive expression of the complex relations with which the biologist has to deal While, therefore, here and there the mathematical methods may aid us, we need a kind and degree of accuracy of which mathematics is absolutely incapable For our accuracy it is necessary often to have a number of data in their correct mutual relations presented to our consciousness at the same time, and this we accomplish by the visual image, which is far more efficient for this service than any other means of which we dispose When we wish to understand a group of complex related details, such as an anatomical structure, we must see them, and if we can not see them no accurate conception of the group can be formed With human minds constituted as they actually are, we can not anticipate that there will ever be a mathematical expression for any organ or even a single cell, although formulæ will continue to be useful for dealing now and then with isolated details Moreover, biologists have to do with variable relations, some of which of course can be put into mathematical form, but we find that even the simplest variations become clearer to us when presented graphically. The value to every student of science of the graphic method has been immense Biologists can work to advantage with quantitative methods, we welcome the increasing use of measurements in biology, we welcome the English journal *Biometrika,* the organ of the measuring biologists—but none the less we refuse to accept the mathematical delusion that the goal of biology is to express its results in grams, meters and seconds. Measurements furnish us with so-called "exact" records, but the aim of science goes beyond the accumulation of exact records to the attainment of accurate knowledge, and the accuracy of our knowledge depends chiefly on what we see The practise of science conforms to this principle, the definite affirmation of which may prove of continuing advantage

No class of records illustrates the value of sight in science more impressively than those made by instruments for registering the time factor The kymographion invented by Carl Ludwig is the prototype of many apparatus In them all a succession of events, like heart beats for example, together with marks showing the time are so registered that they can be seen simultaneously and thus readily compared. If no such apparatus were available much of our most important scientific knowledge would not exist To deprive mankind of microscopes or telescopes would be hardly a more serious blow to science We do not of course depend on our eyes for the notion of time—for the congenitally blind perceive time—but as soon as we wish to know accurately the relation of changing events to time intervals we depend upon having them recorded in a visible form It is the practical acknowledgment of the superiority of the eye as an agent to make clear the correlation of data

When we refer to the history of modern medical science we begin with the anatomist Vesalius, because he reintroduced reli-

ance on seeing in place of reliance on the reading of old authorities.

To dilate longer before this section of the American Association upon the value of seeing is superfluous We have all been trained by dissection and by looking through the microscope, and we will not deny our training, which many of us are engaged in perpetuating.

Scientific records have a far wider scope than ordinary business records, which merely put down details that can not be carried in the memory. Science strives constantly after new ways of recording and demonstrating facts, which would otherwise be imperfectly known, or not known at all, and at the same time of eliminating the personal factor, by getting the data into a form to assist others in the work of verification

Scientific men base their work upon a series of assumptions first, that there is absolute truth, which includes everything we know or shall know, second, that we ourselves are included in this absolute truth, third, that objective existence is real, fourth, that our sensory perception of the objective is different from the reality These conceptions constitute our fundamental maxims, and even when not definitely put in words they guide all sound scientific research Metaphysicians find such maxims interestingly debatable, but science applies them unhesitatingly and is satisfied because their application succeeds Philosophy, ever a laggard and a follower after her swifter sister, has lately and somewhat suddenly termed the scientific habit of work pragmatism and has taken up the discussion of it with delightful liveliness Let us acknowledge the belated compliment and continue on our way

The practical result of the four maxims has been that we further assume that all errors are of individual human origin and that there are no objective errors We make *all* the mistakes, nature makes none. To render the pursuit of new knowledge successful our basic task is to eliminate error, or in other words to decide when we have sufficient proof The elimination of error depends primarily upon insight into the sources of error, which, since methods of all sorts are employed, involves an intimate technical acquaintance with the methods, with just what they can show, with what they can not show and with the misleading results they may produce. In the laboratory training of a young scientific man, one chief endeavor must always be to familiarize him with the good and the bad of the special methods of his branch of science Not until he thoroughly understands the character and extent of both the probable and the possible errors is he qualified to begin independent work His understanding must comprise the three sources of observational error, namely, the variation of the phenomena, the imperfections of the methods and the inaccuracy of the observer. The personal equation always exists, although it can be quantitatively stated only in a small minority of cases

The history of science at large, the history of each branch of science and the personal experience of every active investigator all equally demonstrate that the greatest source of error is in our interpretations of the observations, and this difficulty depends, it seems to me, more than upon any other one factor, upon our unconquerable tendency to let our conclusions exceed the supporting power of the evidence Since generalization is the ultimate goal, we are too easily inveigled into assuming probabilities to be certainties, and into treating theories and even hypotheses as definite conclusions Each generation of investigators in its turn spends

much time killing off and burying older erroneous interpretations The business is seldom accomplished by direct attack, for error perishes only in the light of truth, as microorganisms are said to perish suddenly when struck by ultra-violet rays Owing to the load of false theories, we work like a mental chain-gang and are never unfettered The handicap imposed by wrong hypotheses has always impeded the growth of science Allusion to a few celebrated instances will suffice Phlogiston long prevented chemistry from becoming the peer of other sciences It was a notion which remained alive and dominant until Lavoisier rendered it a mere historical curiosity, by discovering the true principle of combustion The corpuscular theory of light, upheld by Newton, long retarded physics It was got rid of, not by proving it false, but by proving the undulatory theory true. The doctrine of the special creation and fixity of species was universally accepted, although utterly without justification. It vanished from science when the true doctrine of evolution was convincingly established The hypothesis that great epidemics are due to diseases spread by smell, although only the bad guess of ignorance, lasted until modern bacteriology showed us the real causes of infection

The multitude of such experiences, great and small, has gradually created among scientific men a special highly characteristic mental attitude. They regard the majority of the accumulated data and many of the inductions of science as correct This is their estimate of the great body of information which, though personal in its origin, has been in the course of time, so tested and verified that it is looked upon as established and secure. When Asellus in 1622 discovered the lymphatics or so-called lacteals of the mesentery and demonstrated that they convey products of digestion from the intestine, his knowledge was his own, and at first his only. Since then the observations have been so repeatedly verified and of course extended that all uncertainty has vanished from our minds Similarly in innumerable other cases reasonable impersonal certainty has been attained Yet the investigator lives in an atmosphere of concentrated uncertainty, for he is convinced that at any time new data may turn up, and that all generalizations are likely to require modification We might well adopt as our cry—Incredulity towards the known, open credulity towards the unknown.

We think of science as a vast series of approximations and our task is constantly to render our approximations closer to absolute truth, the existence of which we take for granted. We use our approximations as best we may, treating them in large part and at least for the time being as if they were accurately true, yet meanwhile we remain alert to better them This has long been the standard of scientific thought It is the pragmatic attitude of mind, but its new name has not rendered it a novelty

The pivot of all research is adequate proof. It would certainly aid science if some competent philosopher should make a study of the practise of investigators in the various branches of science sufficient to render clear the general principles, by which investigators decide when a new observation or a new induction is sufficiently proven. If we follow the advance of research in any particular direction we soon realize that there is a more or less definite standard of proof, which, though never clearly formulated, is none the less insisted upon, so that any paper which does not come up to this standard is subject to unfavorable criticism Two elements of this

standard we know, the first the elimination of the recognized sources of error, second the repetition of the observations so that the constancy of the phenomenon is assured We can not do more than allude to this theme, which I must leave to the future and to a more competent mind to analyze and develop

To sum up: The method of science is not special or peculiar to it, but only a perfected application of our human resources of observation and reflection—to use the words of von Baer, the greatest embryologist To secure reliability the method of science is *first*, to record everything with which it deals, the phenomena themselves and the inferences of the individual investigators, and to record both truly, *second*, to verify and correlate the personal knowledges until they acquire impersonal validity, which means in other words that the conclusions approximate so closely to the absolute truth that we can be safely and profitably guided by them. The method of science is no mystic process. On the contrary, it is as easily comprehended as it is infinitely difficult to use perfectly and at its best the method supplies merely available approximations to the absolute

We set science upon the throne of imagination, but we have crowned her with modesty, for she is at once the reality of human power and the personification of human fallibility

CHARLES SEDGWICK MINOT
HARVARD MEDICAL SCHOOL

THE FORMATION OF CARBOHYDRATES IN THE VEGETABLE KINGDOM[1]

THE classical discovery of Woehler in 1828 first revealed to chemists the possibility of the synthetic production of those compounds which occur naturally in the members of the animal and vegetable kingdoms Woehler himself evidently realized the importance of his discovery. Thus, in a letter to his old teacher, Berzelius, he wrote [2]

> You may remember how, while I was with you, when trying to make ammonia combine with cyanic acid, I always obtained a crystalline body which gave the reactions of neither the one body nor the other I have just made this crystalline body the subject of a little investigation, preparing it by the action of ammonia on lead cyanate and have discovered it to be nothing less than urea

Then he significantly adds, "This may be taken as an artificial production from inorganic substance"

The idea, however, that such compounds could be formed only through the agency of the vital forces of the living organism was one of such long standing and was so deeply established in the popular belief that even the chemists contemporaneous with Woehler were slow to grasp the full significance of the discovery Berzelius himself was evidently not convinced, since in his text-book published in 1837, nine years after Woehler's discovery, he expressed doubt as to the possibility of being able to discover the differences between the causes of reactions in the living organism and those in the inorganic realm. Likewise Gerhardt[3] wrote seven years later (1842) as follows. "I have shown that the chemist works in a way altogether opposite from living nature. The one burns, destroys, operates by analysis Vital force alone operates by synthesis and reconstructs the edifice torn down by chemical forces"

Other discoveries, however, of a nature

[1] Address of the vice-president and chairman of Section C—Chemistry—at the Minneapolis meeting of the American Association for the Advancement of Science.

similar to Woehler's followed, although somewhat tardily Kolbe in 1845 showed that it was possible to synthesize acetic acid from its elements Berthelot in 1854 likewise built up the fats In the light of such achievements the most skeptical could no longer maintain the old view concerning the impossibility of building up in the laboratory from inorganic sources those compounds naturally occurring in the living organism The recognition of this great truth opened up to chemists a new line of investigation and from that time the synthetic preparation of organic compounds has ever been a fruitful field of research It has sometimes seemed to me, however, that in the enthusiasm over the discoveries which chemists have made in this field of investigation we are inclined to over-estimate the work done, great as that may be, and perhaps unintentionally convey the impression that the chemical changes taking place in the living organism are thoroughly understood and can be duplicated in the laboratory While of course it is true that many of the compounds in the living organism have been synthesized and that the number of such syntheses is constantly increasing, yet we must not forget that the chemist's method has never been, in detail at least, the method of nature Indeed, as a rule they are widely divergent We are apt to employ powerful reagents many of which so far as is known do not exist in the organism nor in the mediums from which it draws its sustenance The drastic treatment to which these substances are often subjected and the temperatures at which the reactions are carried on are all in the greatest contrast to the conditions which prevail in the organism in which the natural synthesis is effected In a few cases the laboratory methods employed more nearly approach the conditions which prevail in nature and such syntheses always have a greatly added interest at least from a theoretical standpoint Thus the observation of Loew[4] that a sugar-like compound could be formed by the condensation of formaldehyde was exceedingly important, but this importance was greatly enhanced by the fact that this condensation could be effected by the action of mild alkalis or even neutral substances at ordinary temperatures—conditions which approximate those existing in the growing plant Likewise the importance of the observations of Lobry de Bruyn and van Ekenstein[5] that the three hexoses, namely, mannose, fructose and dextrose, are mutually convertible, lay largely in the fact that these transformations could be made to take place at ordinary temperatures under the influence of reagents that may exist in the soil The study of such problems as these has become not only one of the most alluring and fascinating in the fields of research in organic chemistry, but their solution is fraught with the greatest significance, since it will be a step in the direction of gaining some understanding of the mysteries of life itself

Inasmuch as the carbohydrates play such an important part in the economy of the vegetable kingdom, it is quite natural that the investigations of the problems pertaining to the synthesis of compounds in the living organisms have been largely directed towards this class of compounds. Since it is impossible in a short time to discuss with any thoroughness the various researches carried out in this field of investigation I will confine myself to those which have some important bearing upon the well-known hypothesis proposed by Baeyer, with a view of determining, if pos-

[4] *J prakt Chem*, 33, p 321.

[5] *Ber. d chem Gesell*, 28, p. 3078

sible, its standing in the light of modern discoveries.

In 1861 there appeared in the *Annalen der Chemie* and simultaneously in the *Comptes rendus* a short article by a Russian chemist, Butlerow,[6] in which he described the formation of a sugar-like substance (methylenitan, he termed it) through the interaction of trioxymethylene and calcium hydroxide in an aqueous solution. Although the resulting substance was optically inactive and was not fermentable, Butlerow nevertheless was sure that the sweet syrup which he obtained contained a sugar, for he concludes his accounts with the statement that his results furnish the first example of the synthesis of a sugar-like body. These results of Butlerow proved to be of the greatest importance, not only because of the facts revealed, but also because they served to suggest to other investigators the method of attacking the general problem of the synthetic production of sugars. Moreover, they undoubtedly served as an experimental groundwork upon which Baeyer a few years later based his well-known hypothesis.

The essential assumptions of Baeyer's hypothesis, viz., the production of formaldehyde through the interaction of carbon dioxide and water, and the subsequent polymerization of this to a sugar, are well known to all and require no discussion. It may be of interest, however, to recall some of the reasons advanced by Baeyer in setting forth these assumptions.

The original statement of the theory was published in the *Berichte* just forty years ago (1870) and was entitled "Ueber die Wasserentziehung und ihre Bedeutung fur das Pflanzenleben un die Gahrung."[7]

[6] *Annalen der Chem.*, 120, p. 295; *Compt. rend.*, 53, p. 145.

[7] *Ber. d. chem. Gesell.*, 3, p. 67.

Baeyer here calls attention to the fact that in the transformation of the compounds of carbon, hydrogen and oxygen, the separation of water plays just as weighty a rôle as do the processes of oxidation and reduction. He then discusses the groups of those reactions in which water is formed by the union of hydrogen and oxygen withdrawn from the interacting compounds. Among the various reactions are those in which the water removed is formed by the union of hydrogen taken from one molecule with an hydroxyl group taken from a different molecule—an "*aussere Condensation*," as Baeyer termed it. To illustrate this he gives his interpretation of the reaction involved in Butlerow's sugar synthesis. Although Butlerow had used trioxymethylene, Baeyer evidently felt justified, because of the intimate relation between this compound and formaldehyde, in assuming that the reaction actually taking place is one between the different molecules of formaldehyde. Considering that formaldehyde in aqueous solution is in the hydrated form, Baeyer shows that by the splitting off of water formed by the union of a hydroxyl group from one molecule of formaldehyde with the hydrogen from another molecule and the union of the two remaining residues through the resulting free affinities, it is easy to understand how from six molecules of formaldehyde the hexoses might result. Baeyer even deduced two possible structural formulas for a hexose based on this interpretation of the course of the reaction, one of these being the well-known aldehyde formula. Likewise he shows how by the condensation of three molecules of formaldehyde one would expect to obtain an aldehyde of glyceric acid. The older view of Liebig to the effect that the fruit acids are the intermediate products from which the sugars result, Baeyer rejects in favor of

the one that the sugars are formed directly from the carbonic acid. This formation could be satisfactorily accounted for as follows. Through the combined action of chlorophyll and sunlight carbon dioxide suffers dissociation into carbon monoxide and oxygen. The oxygen is evolved while the carbon monoxide combines with the chlorophyll much as it does with the hæmoglobin of the blood. By the action of hydrogen, obtained by the dissociation of water, the carbon monoxide is then changed into formaldehyde from which the sugar results by condensation. The essential points in Baeyer's hypothesis are therefore, first, the production of formaldehyde from carbon dioxide and water, and second, the formation of sugars by the polymerization of the aldehyde. Other investigators have suggested certain modifications of this theory, mainly in the method of generation of the formaldehyde. Thus, Erlenmeyer[8] in 1877 from certain observations made on the action of water on hydroxy acids was led to conclude that the carbonic acid would be acted upon by water under the conditions existing in the plant with the production of formic acid and hydrogen peroxide in accordance with the following equation: $HO.COOH + HOH \rightarrow H_2O_2 + H.COOH$. The formaldehyde would then result from the reduction of the formic acid. Bach,[9] on the other hand, assumes the decomposition of the carbonic acid directly into formaldehyde and an unstable percarbonic acid, H_2CO_4, which would break down into hydrogen peroxide with regeneration of carbon dioxide. Usher and Priestley[10] as well as Pollacci[11] have also suggested certain modifications of the general assumptions.

The principal researches which have a direct bearing on the validity of Baeyer's hypothesis may be classified in regard to their bearing on the following problems: First, Is it possible to produce formaldehyde in the laboratory from carbon dioxide and water under conditions approximating those existing in the plant? Second, Is formaldehyde actually present in the living organism? Third, Is it possible for the organism to assimilate formaldehyde? Fourth, Is it possible to produce carbohydrates directly from formaldehyde?

It is my purpose to discuss briefly the more important researches carried out in these fields of investigation.

PRODUCTION OF FORMALDEHYDE THROUGH THE REDUCTION OF CARBONIC ACID

The production of formaldehyde through the reduction of water and carbon dioxide has been the subject of numerous researches. Maly[12] in 1865, and in more recent time Lieben[13] (1895), attempted this reduction by employing various amalgams as reducing agents. Royer[14] in 1870 and Coehn and Jahn[15] in 1904, on the other hand, studied the effect of electrolytic hydrogen on the carbonic acid. In all these cases, however, the reduction resulted not in the formation of formaldehyde, but of formic acid. In 1893 Bach[16] attempted to carry out the reaction under conditions closely approximating those existing in the plant. As a substitute for the chlorophyll in the plant Bach, relying upon the well-known sensitiveness of uranium compounds to light, used uranium acetate as a chemical and photo-sensitizer. Carbon dioxide was passed through flasks filled

[12] *Annalen der Chem.*, 135, p. 119.

[13] *Wien. Monats.*, 16, p. 211; 18, p. 582.

with a 1.5 per cent solution of uranium acetate. When the experiment was carried out in the sunlight there was obtained a precipitate of the hydroxides of uranium together with a small amount of peroxide. The results are explained on the supposition that the carbonic acid is resolved into formaldehyde and a percarbonic acid, H_2CO_4, in accordance with the following equation: $3H_2CO_3 = CH_2O + 2H_2CO_4$. The percarbonic acid as fast as formed breaks down into hydrogen peroxide and carbon dioxide. To support this interpretation of the course of the reaction, Bach refers to the work of Wurster,[17] who claimed to have demonstrated the presence of hydrogen peroxide in plants, although Wurster's results had been strongly challenged by Bokorny.[18] In 1898 Bach[19] again returned to the problem, this time using palladium as a catalyzer. Carbon dioxide was passed through water containing palladium held in suspension. In the clear liquid obtained by filtering off the palladium Bach claims to have established the presence of formaldehyde.

While the experiments of Bach are ingeniously conceived and are of great interest, his interpretation of the results do not appeal to one as at all conclusive. The most that can be said is that the generation of formaldehyde and hydrogen peroxide under the conditions of the experiments is probable. Their presence must be regarded as inferred rather than proved. It is not strange therefore that his results have been criticized. In 1904 Euler[20] repeated the work and concluded that the carbon dioxide in Bach's experiments did not enter into the reaction at all since exactly the same results are obtained if one substitutes a current of hydrogen or nitrogen for the carbon dioxide.

On the other hand, Usher and Priestley[21] in 1906 reported that "the experiments of Bach have been repeated and confirmed, both as to the production of peroxide and formaldehyde." Oddly enough, however, they gave no account as to their manner of confirming these results, and since Bach himself rather inferred than proved the presence of these two compounds the statement of Usher and Priestley is not wholly satisfactory. In order to meet the criticism that the production of formaldehyde in Bach's experiments may have resulted from the reduction of the acetic acid which would undoubtedly be formed by the hydrolysis of the uranium acetate used, Usher and Priestley[22] in a later article described a series of experiments in which uranium sulphate was substituted for the uranium acetate. In these experiments no formaldehyde could be detected, although the authors report that "a study of the reactions involved favors the view that it is formed as a transitory intermediate product." In their original work Usher and Priestley were led to conclude from experiments on plants (*Elodea* were used) that the generation of formaldehyde in the plant from carbon dioxide and water is not a vital process at all since small plants of *Elodea* in which all life had been destroyed by immersion in boiling water accumulated perceptible amounts of formaldehyde when exposed to sunlight in a moist atmosphere of carbon dioxide. The tests for formaldehyde were made directly upon the leaves as well as upon the distillate from the leaves. The principal tests employed were (*a*) the development of color in Schiff's reagent, (*b*) the formation of methyleneaniline with

[22] *Proc. Royal Soc.*, B, 78, p. 318.

aniline, and (c) the formation of hexamethylene tetramine with ammonia and bromine Acting on the conclusion that the production of formaldehyde in the plant is not a vital process, these investigators in a later article described a series of experiments in which they attempted to produce formaldehyde from water and carbon dioxide in the laboratory by reproducing the conditions existing in the plant Plates of glass were painted over with gelatine, which in turn was coated with a thin film of chlorophyll The plates so prepared were placed in a moist atmosphere of carbon dioxide and exposed to the sunlight The chlorophyll was employed to effect a reduction of the carbon dioxide and water into formaldehyde by acting as a photo-sensitizer, while the gelatine was used in the hope that it would absorb all formaldehyde as fast as formed, thus removing it from the sphere of action After the exposure of the plate the gelatine was removed and tested for formaldehyde by the tests previously mentioned and in all cases the aldehyde was found to be present

If the interpretation of these results, as given by Usher and Priestley, is correct, this work is of the very highest value, not only in its relation to Baeyer's hypothesis, but especially because the reduction of carbon dioxide and water to formaldehyde in plants is shown to be a laboratory and not a vital process It must be stated, however, that the conclusions reached have been contradicted by Ewart,[23] who insists that the gelatine used in the experiments will give the test for formaldehyde just as well before exposure to carbon dioxide and light as after such exposure, and that even granting the generation of formaldehyde under these conditions, it is, to say the least, just as reasonable to conclude that it is derived from the decomposition of the chlorophyll in the presence of oxygen as it is to conclude that it is formed from carbon dioxide and water

Some of the most interesting results in this field of investigation have been obtained by Lob,[24] who attempted to gain some insight into the changes taking place in the plant by substituting the action of the silent electric discharge for that of the sunlight as well as of any catalytic agent or enzyme present in the plant In this way it was shown that formaldehyde is a direct reduction product of carbon dioxide and water vapor Lob claims, and with justice, that his experiments bring the first positive proof that formaldehyde is a direct reaction product of moist carbon dioxide

In 1907 Fenton[25] attempted the generation of formaldehyde directly from carbonic acid by passing a current of carbon dioxide for a number of hours through pure water in contact with several rods of amalgamated magnesium He concludes that "the solution gives slight but unmistakable indications of formaldehyde" with certain standard color tests So far as I know, these results have not been challenged

The most recent work, as well as probably the most significant, is that of Berthelot and Gaudechon[26] By the action of ultra-violet light on a mixture of carbon dioxide and water vapor, these investigators have succeeded in obtaining formaldehyde together with carbon monoxide and oxygen. Under the same conditions, carbon monoxide and water vapor gives rise to formaldehyde, carbon dioxide and hydrogen.

THE EXISTENCE OF FORMALDEHYDE IN PLANTS

As an immediate result of Baeyer's hypothesis attempts have been made to detect formaldehyde in plants of various species and grown under various conditions The results of these investigations are not at all satisfactory and indeed consist largely in affirmations and denials The problem, however, is not a simple one In the first place formaldehyde, if present at all, can only be present in very minute quantities because of its very great toxicity, and while it is true that extremely delicate tests have been advanced for formaldehyde it is likewise true that these tests have been subjected to considerable criticism. Moreover, it is possible that such delicate tests might be influenced by the presence of various other substances present in the plant

In 1881 Loew and Bokorny[27] advanced the theory that the vital force of the living protoplasm is essentially connected with the presence of aldehyde groups in the substance forming the protoplasm When certain algæ, for example, were immersed in a dilute solution of silver nitrate the living cells were found to be darkened when examined under the microscope The authors attribute this change in color to the reduction of the silver salt by the aldehyde present Plants previously immersed in boiling water to destroy the life of the protoplasm failed to give the test, hence the authors conclude that the aldehyde group disappears with the life of the plant

In the same year Reinke[28] by macerating certain green leaves (those of the grape vine, the poplar, the willow and conifers, were tested) and distilling the mass in a current of steam obtained a liquid having strong reducing powers which he attributed to the presence of an aldehyde Moreover, the aldehyde must be an easily volatile one, for it is present chiefly in the first portions of the distillate While not able to prove the exact identity of the aldehyde Reinke concluded that it is formaldehyde These reactions were obtained only in the case of chlorophyll-bearing plants Reinke suggested that the reducing power of the algæ observed by Loew and Bokorny might be due to the presence of formaldehyde in the plant This statement led to further studies by both investigators and the publication of several articles[29] in which each held to his original interpretation of the results, although Reinke was forced to admit that he had not definitely proved the presence of formaldehyde in the distillate from the plants, but only the presence of an easily volatile aldehyde

Mori[30] (1882) experimenting with the leaves of the rose bush and of oats obtained results similar to those of Reinke He also tested the plant by adding a few drops of Schiff's reagent directly to portions of the plant, whereupon a red color gradually resulted Loew and Bokorny[31] claim, however, that the development of the color in Mori's experiments was due to the evaporation of the sulphurous acid in Schiff's reagent and show that this reagent gradually becomes colored by mere exposure to air

In 1889 Polacci[32] reported the results of an extended series of investigations from

which he concluded that formaldehyde is undoubtedly present in the green parts of living plants when exposed to sunlight He experimented directly with the growing plant, as well as with the liquid obtained by distilling the leaves in a current of steam Twigs were bent down from the growing plant into cylinders containing Schiff's reagent It was found that when the experiment was carried on in the sunlight the red color gradually developed, which result was attributed by the investigator to the production of formaldehyde While the results obtained by the tests made directly upon the leaves were only suggestive and not conclusive, the distillate from the leaves Polacci affirms undoubtedly contains formaldehyde itself Many tests were employed Some of these were of a general character, while others were definite for formaldehyde itself Special stress is placed on (*a*) the color test obtained by successive additions of phenylhydrazine, nitroprussiate of sodium and alkali, (*b*) the color test with sulphuric acid and codeine, (*c*) Trillat's color test with an aqueous solution of dimethyl aniline in the presence of acetic acid and lead peroxide, (*d*) the reaction with phenylhydrazine, (*e*) the color test with phenol and sulphuric acid A short time after the publication of the results of Polacci's experiments two other Italian investigators, namely Plancher and Ravenna,[33] reported a series of similar experiments, but failed to find any conclusive proof of the presence of formaldehyde in plants The formation of color in Schiff's solution under the conditions of Polacci's experiment was attributed not to the presence of formaldehyde, but to the "active" oxygen evolved by the plant in the process of assimilation They likewise claimed that the tests which Polacci employed for the detection of formaldehyde in the distillate from green leaves are untrustworthy In order to determine whether formaldehyde, if present in the green leaves, would actually distill over or would remain combined with compounds in the plants, these investigators added a very dilute solution of formaldehyde to leaves before distillation and then tested for formaldehyde in the distillate The results showed that the amount of formaldehyde which must be present in the leaves in order to respond to conclusive tests in the distillate is so large that it would destroy at once the vitality of the plants. Polacci's results have also been criticized by Czapeck[34] as being indefinite Euler,[35] on the other hand, confirms his results, although he expresses the opinion that the formaldehyde is not present in a free state in the plant, but is liberated from its condensation products by the process of distillation. In a more recent article Polacci[36] refers to the criticisms of his investigations and defends his original conclusions with great vigor

Among the other investigators may be mentioned Grafe[37] as well as Kimpflin,[38] both of whom maintain that formaldehyde is undoubtedly present in the growing plant The former investigator used a solution of diphenylamine in sulphuric acid as a test, claiming that this reagent gives a green coloration with exceedingly minute quantities of the aldehyde. Kimpflin, on the other hand, recognizing that formaldehyde, if present at all, can only be present in minimal amounts, ingeniously attempts to store up the compound as fast as formed until a sufficient quantity is obtained to respond to the tests. To do

[38] *Compt rend.*, 144, p 148

this he introduces into the tissue by means of a capillary tube a solution of sodium acid sulphite and methylparamidometacresol. After this injection the plant is exposed to the light for a time, when a section of the leaf is placed in absolute alcohol and subsequently examined under the microscope in the presence of a drop of water The presence of the aldehyde is shown by the formation of a red color. According to the author, the aldehyde as fast as produced combines with the acid sulphite to form the addition compound which is stable in the absolute alcohol. Upon the addition of a drop of water, however, the aldehyde is liberated and forms a characteristic color with the cresol.

While Usher and Priestley[39] claim to have definitely proved the presence of formaldehyde in the dead plant according to the method described above, they merely infer its presence in the living plant In fact, they assert that it would be useless to look for it in a healthy living plant because of the rapidity with which it would be transformed into other substances

In a recent article Bokorny[40] criticizes the work of Kimpflin and others and maintains that the amount of formaldehyde which would have to be present in the plant in order to respond to any of the known tests would certainly destroy the vitality of the plant He maintains, however, that it is undoubtedly present, but in such minute quantities at any given period that the only hope for its detection lies in the discovery of some agent which would combine with the aldehyde as fast as generated to form a compound that is not toxic to the plant and from which compound it could again be recovered in quantities sufficient to respond to the standard tests It may be added that this is practically what Kimpflin attempted.

THE ASSIMILATION OF FORMALDEHYDE BY PLANTS

No single evidence perhaps would count so much towards corroborating Baeyer's hypothesis as the proof of the power of plants to assimilate free formaldehyde with the production of carbohydrates It is natural therefore that many experiments have been made to ascertain just what effect formaldehyde has on the growing plant In conducting such experiments naturally the formaldehyde would have to be administered in very dilute solutions, moreover, the amount of such solutions would have to be large in order to obtain a sufficient amount of formaldehyde to effect a sensible amount of any assimilation product

The first investigator to make any extensive study of this question was Bokorny,[41] who attempted to grow certain water plants (green filaments of *Spirogyra*) in dilute solutions of formaldehyde. He found that formaldehyde, even in solutions of 1 to 50,000, was fatal to the growth of the plant Next the attempt was made to substitute for the free formaldehyde some substance which under the influence of the plant would slowly decompose, giving formaldehyde as one of the decomposition products Such a substance Bokorny found in methylal which decomposes into formaldehyde and methyl alcohol and also in the sodium acid sulphite addition product of formaldehyde By the use of these compounds Bokorny hoped to diminish the concentration of the actual aldehyde to the minimum and yet by its constant formation furnish a sufficient amount of it to

[41] *Ber d. bot Gesell*, 1888, p 119; *Chem. Zeit*, 44, p 525; *Phar. Post*, 36, p 153; *Biolog. Centralbl*, 12, No. 16 and 17.

the plant to enable one to prove whether or not assimilation actually takes place. It was found that the *Spirogyra* immersed in a solution of either of these substances under certain conditions continue to grow and produce starch in the absence of carbon dioxide These results must be regarded as strong corroborative evidence in favor of the view that plants have the power of directly assimilating formaldehyde, they are not conclusive, however, since there is no actual proof that the compounds are decomposed by the plants previous to assimilation

Later Bouillac and Giustiniana[42] succeeded in growing ordinary white mustard in solutions containing traces of formaldehyde It is interesting to note that a certain amount of light was necessary, however, for the growth of the plant

Treboux[43] also reports that he has successfully grown the *Elodea* in solutions of one part of formaldehyde in one hundred thousand, but that no starch was formed; hence he concludes that his results are opposed to the general belief that formaldehyde is directly polymerized to carbohydrates

Usher and Priestley[44] in the investigations referred to above likewise report a case of starch formation in a solution containing one part of formaldehyde in one hundred thousand

In 1908 Bokorny[45] reported some experiments in which he succeeded in proving that spirogyra can assimilate such substances as glycerol, sucrose and even traces of formaldehyde itself when present in dilute solutions A year later[46] he again reported some experiments in which he attempted to grow water cress under a bell jar over a 30 per cent solution of sodium hydroxide containing small amounts of formaldehyde and concludes that the upper portions of the plant undoubtedly absorb aldehyde vapor This assimilation can take place in the absence of both oxygen and light

Likewise Grafe and Vieser[47] have grown seedlings of *Phaseolus vulgaris* in air free from carbon dioxide but containing formaldehyde and report that plants under such conditions grow more rapidly than in normal air

So far as I know, no attempts have been made to ascertain the effect of glycolaldehyde and glycerose upon the growth of the plant It is probable that these compounds are intermediate products in the formation of a sugar by the polymerization of formaldehyde One would naturally expect therefore that they would be assimilated by the growing plant Moreover, they would be better adapted than formaldehyde for such investigations, since they are relatively less toxic, and hence could be used in larger amounts.

SYNTHETIC PRODUCTION OF SUGAR FROM FORMALDEHYDE

It will be recalled that Butlerow's methylenitan was synthesized not from formaldehyde itself but from a closely related compound, trioxymethylene Loew[48] in 1886 was the first to build up a sugar directly from formaldehyde, using mild alkalis as condensing agents. Three years later Loew[49] succeeded in obtaining a purer product (formose) by using the oxides of lead and magnesium as condensing agents. In the meanwhile Fischer[50] was carrying out those brilliant researches in which the

[42] *Compt rend*, 136, p 1155

[43] "Flora," 92, p 73

[44] *Proc Royal Soc*, B, 77, p. 370

[50] *Ber d chem Gesell*, 20, pp. 1093, 2566, 3384

synthesis of fructose was effected first from acrolein and later from glycerol. The whole subject of the action of alkalis upon formaldehyde has been taken up in recent years by Euler,[51] who has made a careful study of the course of the reaction and the conditions affecting it It is especially interesting to note that this investigator has succeeded in synthesizing a sugar from formaldehyde through the agency of calcium carbonate as a condensing agent The interest here lies chiefly in the fact that the formation of sugar may be effected by a substance universally distributed in the soil It is interesting to note that Euler in this way showed that the simplest of sugars, viz., glycolaldehyde, is produced as an intermediate product The principal sugar finally formed is a pentose, namely, (*dl*)-arabino-ketose Lob[52] has recently effected similar condensations by the use of zinc as well as zinc carbonate.

Equally important are the results which have been obtained through the action of the silent electric discharge Berthelot,[53] in this way, produced from a mixture of carbon dioxide, water and hydrogen a substance having the properties of a carbohydrate With carbon monoxide and hydrogen he obtained a similar product which appeared to be a polymer of formaldehyde. Likewise Slosse,[54] from carbon monoxide and hydrogen, obtained a crystalline, fermentable sugar

The investigations of Lob[55] in which he produced formaldehyde directly from carbon dioxide and water vapor through the influence of the silent electric discharge have already been referred to. Under the same conditions this investigator has been able to polymerize the aldehyde so formed into glycolaldehyde and this in turn into a hexose The formation of a sugar from carbon dioxide and moisture has thus been effected through the agency of the energy of the silent electric discharge. It may be added that patents have been taken out for the synthetic production of sugar under this general method

Taken as a whole, the results of the investigations would seem to corroborate Baeyer's original assumptions The transformation of carbon dioxide and water into formaldehyde and the subsequent polymerization of this into a sugar under conditions approximating those existing in the plant may be regarded as accomplished While the evidence advanced can not be regarded as showing beyond doubt the presence of free formaldehyde in the plant, yet it is plain that the failure to detect its presence can not be regarded as fatal or as even opposed to Baeyer's theory In fact, one would naturally expect that because of its great activity, its polymerization would keep pace with its formation and that the tests for its presence would therefore be negative On the other hand, it can not be doubted but that plants have the power to directly assimilate formaldehyde While certain objections have been urged against Baeyer's hypothesis and other radically different ones[56] have been advanced, yet it would seem from the present indications that further progress in our knowledge of the formation of carbohydrates in the vegetable kingdom probably will be made along the lines originally pointed out by Baeyer

In the study of the results of these investigations one is impressed with the large number of conflicting statements Certainly one would not turn to these re-

ports as an argument for the exactness of chemical science As a rule, however, the disagreements relate not so much to the observations as to their interpretation Of course it is useless to expect investigators to agree upon the question as to whether or not formaldehyde is present in the plant, until they first can agree in regard to the tests for formaldehyde which shall be considered as conclusive Again while this general subject is primarily a chemical one, yet many of the investigators have been men trained rather in other fields of work It would seem that the chemist, or better, perhaps, the chemist and the botanist working conjointly, ought to be able to make surer progress in such investigations The problem is an exceedingly complex one. Its solution involves many reactions at present but little understood—such as the nature of catalytic and enzymic action and the formation of asymmetric compounds It is probable also that other forces not yet investigated may enter into the reactions by which these compounds are formed Stewart[57] has even suggested that it is "not improbable that the rotation of the earth or terrestrial magnetism or the motion of the earth around the sun may have some effect" There is no doubt, however, but that progress is being made It is also undoubtedly true that many of the researches now being carried on in our laboratories will be found to have a more or less direct bearing upon the general question; and it has been partly my object in discussing this topic to emphasize this fact in order that the results of our investigations, whenever applicable, may be directed towards the solution of this problem

WILLIAM McPHERSON
OHIO STATE UNIVERSITY

[57] "Stereochemistry," London, 1907, p 535.

THE AMERICAN MUSEUM OF NATURAL HISTORY

DR HERMON C BUMPUS has resigned the directorship of the American Museum of Natural History and has accepted the position of business manager to the University of Wisconsin This announcement was made on January 20 by Mr. Seth Low, chairman of a special committee of the trustees appointed to consider the administration of the museum He gave out the following statement

Director Bumpus notified the trustees of the American Museum of Natural History at a special meeting held yesterday afternoon that he had accepted an appointment as business manager for the University of Wisconsin Accordingly he presented his resignation as director, which was accepted The administrative difficulty in the museum is thus terminated

The questions raised as to the respective duty and authority of various officers in the museum seemed to the board important enough to be referred to a special committee, which was appointed on November 30, 1910, to give a hearing to the director and to consider his criticisms The committee, which consisted of Anson W Hard, Adrian Iselin, Jr, Percy R Pyne, Felix M Warburg and Seth Low (chairman), went into every criticism very thoroughly They found nothing to justify the sweeping statements which had been made, and the specific criticisms of President Osborn, when sifted, were found to be either unimportant or not sustained The committee and the board believes that the administration of President Osborn has been wise, efficient, far sighted and public-spirited, and that the financial management has been sound and constructive

THE CARNEGIE INSTITUTION OF WASHINGTON

IT was announced on January 20 that Mr Andrew Carnegie had added $10,000,000 to the endowment fund of the Carnegie Institution of Washington. The institution was established in 1902 with a gift of $10,000,000, and Mr Carnegie recently added $2,000,000 These gifts consist of preferred bonds of the Steel Corporation bearing five per cent. interest and their market value is considerably above their par value Mr Carnegie's gifts to

public purposes now amount to about $200,000,000.

SCIENTIFIC NOTES AND NEWS

At its last meeting the Rumford Committee of the American Academy of Arts and Sciences made the following grants: To Professor Joel Stebbins, of the University of Illinois, $200, in further aid of his researches on the selenium photometer. To Professor M. A. Rosanoff, of Clark University, $300, in further aid of his investigation on the fractional distillation of binary mixtures.

The Society of American Bacteriologists will meet in Washington, D. C., the last week in December of this year. The officers are: *President,* F. P. Gorham, Brown University; *Secretary,* Charles E. Marshall, Michigan Agricultural College.

At the annual meeting of the New York Pathological Society, held at the Academy of Medicine, on January 11, the following officers were elected: *President,* Dr. William G. MacCallum; *Vice-president,* Dr. John H. Larkin; *Secretary and Editor,* Dr. A. M. Pappenheimer; *Treasurer,* Dr. Francis C. Wood. Dr. T. M. Prudden and Dr. E. K. Dunham were reelected trustees of the society to serve for a term of three years. The next meeting will be held in conjunction with the Philadelphia Pathological Society in Philadelphia on February 9.

Mr. S. P. Jones, formerly assistant state geologist of Georgia, is with the New Jersey Geological Survey.

Mr. C. E. Bradley has resigned as chemist of the Agricultural Experiment Station at Corvallis, Oregon, to accept the position of research chemist with the Rubber Regenerating Company, of Mishawaka, Indiana.

The program of the Section of Astronomy, Physics and Chemistry of the New York Academy of Sciences on January 27 included the following papers on Aviation: "Experiences in Aviation," Mr. Clifford B. Harmon; "Practical Utility of Flying Machines," Mr. Hudson Maxim; "The Aeroplane" (illustrated by lantern slides), Lieutenant Phillip Wilcox, U. S. A. R.; "Taking the First Photographs of the Flights of the Wright Brothers at Kitty Hawk, North Carolina" (illustrated by lantern slides), Mr. James H. Hare.

Professor W. P. Mason, of Rensselaer Polytechnic Institute, delivered a lecture before the Williams College Natural Science Club on "Water and Disease," on January 19.

The Smithsonian Institution is about to come into possession of a bequest by the recent death of George W. Poore, Esq., of Lowell, Mass. His will provides, after certain minor legacies, that the residue of his estate be given to the Smithsonian Institution to form the Lucy T. and George W. Poore Fund, the income of which is to be used for the purposes for which the institution was founded. The will further requires that this fund shall be kept separate from all other funds and the income to be added to the principal until it shall have reached the sum of $250,000. Mr. Poore explains in his will that he makes this bequest in the hope that "it will form an example for other Americans to follow by supporting and encouraging so wise and beneficent an institution as I believe the Smithsonian Institution to be."

Mr. Alcan Hirsh, a graduate student in electro-chemistry at the University of Wisconsin, has succeeded in producing about half a pound of metallic cerium, one of the rare elements which heretofore has been isolated only in small quantities.

Sir Ernest Shackleton hopes in the course of next year to undertake an expedition to Spitzbergen, spending two and a half or three months in the islands. His party will probably consist of six, including Mr. J. Murray, the biologist, and other members of the *Nimrod* expedition.

Hon. Charles H. Sherrill, United States Minister to Argentine Republic, will give an address on February 16 to the officers and students of Columbia University on the opportunities for American engineers in public works and other fields in Argentine.

Dr. H. W. Wiley, chief of the division of chemistry of the Department of Agriculture

lectured before the Chemical Society of Washington and Lee University on January 13, his subject being "Some of the less Obvious Advantages of Chemical Study." Dr. J. W. Mallet, of the University of Virginia, is to lecture before the society on February 17.

PROFESSOR GEORGE T. MOORE recently gave a series of lectures before the Washington University Association on "What goes on in the Ground."

WITH a greatly increased equipment the new laboratory of St. Luke's Hospital, New York, has recently been opened. Some changes have been made also in the personnel of the laboratory staff, which now includes Dr. Francis C. Wood, director, Dr. Karl M. Vogel, clinical pathologist, Dr. J. Gardner Hopkins, bacteriologist, Dr. William H. Woglom, pathologist, Dr. George C. Freeborn, assistant in pathology, and Dr. N. B. Foster and Dr. H. O. Mosenthal, assistants in chemistry.

THE New York Zoological Park has received from Mr. E. B. Bronson, from Quito, Ecuador, a fine specimen of the Spectacled Bear (*Ursus ornatus*), captured in the Andes of Ecuador. Excepting the Æluropus, of eastern Tibet, this is the rarest bear species either alive in zoological gardens or in museums. The specimen is temporarily exhibited in one of the large cages of the small mammal house, where it will remain until the new series of bear dens now under contract and in the course of erection is completed, which will be about June first.

TWENTY-THREE cases of zoological material representing several hundred skins of birds and mammals have been received by the American Museum of Natural History as the first shipment of specimens from the Stefánsson-Anderson Arctic Expedition.

AT the last meeting of the Oregon Academy of Sciences a number of new members were elected. The subject of the evening was "The Single Tax," by C. H. Chapman, one of the editors of the *Oregonian*. The meeting was held early in the evening preceded by a dinner which was attended by about sixty-five persons. It was decided to use this plan for a part of the monthly meetings this year combining social and scientific features.

A GERMAN edition of "Light Waves and their Uses," by Professor Albert A. Michelson, head of the department of physics of the University of Chicago, has just been issued by the publishing house of Johann Ambrosius Barth in Leipzig. The translation was made by Dr. Max Ikle. The lectures which constitute the book were originally delivered by Professor Michelson in the Lowell Institute in 1899. The translator has added a bibliography of writings bearing on this subject published since 1880.

WE learn from *Nature* that the Agenda Club, which was formally inaugurated by a banquet recently, proposes to organize effort, knowledge and influence for the purpose of getting things done which need doing for the benefit of the community. The movement first acquired publicity through "An Open Letter to English Gentlemen" in the *Hibbert Journal*. This letter, and the club itself, appeal frankly to the idealism and the goodwill of the best men, but an equally essential characteristic of the club is to organize the altruism of its members with at least as much efficiency as that of the most successful modern business. The club expressly enunciates its need of guidance by scientific men in determining the agenda to be undertaken and in many details of its work. It is a coordinating society, and not one that overlaps the work of other bodies devoted to special purposes. Among other methods to be employed is that of the most extensive publicity. It contemplates the encouragement of research, especially in social science, and its scheme includes groups of associates, among which are mentioned engineering, literature, medicine and science.

THE Berlin correspondent of the *Journal* of the American Medical Association writes that on October 26 the Berliner medizinische Gesellschaft celebrated its semi-centennial. The memorial meeting was of peculiar importance, as this society is not only the largest medical association in Berlin, but also one of

the most noted and largest in Germany and can look back on a notable past. The society was formed by the union of two Berlin societies The older of these was founded in 1844 as a society for scientific medicine and the younger was the Verein Berliner Aerzte, founded in 1858 In order to obviate any difficulties arising from the union of the two societies, which took place in 1860, Rudolf Virchow resigned his position as president of the society for scientific medicine, in favor of Albrecht v Grafe, the president of the other society The Berlin Medical Society, in spite of the separation from it of numerous special associations, of which that founded by v Leyden as the Verein fur innere Medizin was the first, has still remained the central point of scientific medical activity in Berlin, and almost every Berlin physician considers it his duty to belong to it, so that at present it has more than 1,600 members. As a result of the participation of the university teachers, the scientific proceedings are always valuable and a number of important discoveries have been presented here for the first time As successors of v. Grafe, Bernhardt von Langenbeck, Rudolf Virchow, Ernst v Bergmann, and finally H. Senator have held the office of president. Robert Koch, Helmholtz and Pasteur were made honorary members, a distinction which has seldom been bestowed. On the occasion of the semi-centennial the number of honorary members was considerably increased, including in addition to two living members of the society, two physicians practising in Berlin, Professor Waldeyer and the surgeon general of the Prussian army, v. Schjerning, Naunyn (Baden-Baden), Exner and Fuchs (Vienna), Golgi, Armauer-Hansen (Christiania), Abraham Jacobi (New York), Fr Koranyi (Budapest), Keen (Philadelphia), Kitasato (Tokio), Laveran (Paris), Lépine (Lyons), Lister, Murri (Bologna), Pawlow (St. Petersburg), Ramon y Cajal (Madrid), Retzius (Stockholm), Salomonsen (Copenhagen) and Röntgen (Munich) Senator was elected honorary president. On the festival day it was announced that so far $15,000 (63,000 Marks) had been subscribed by the members for the building of the projected Virchow House, which is to be the special home of the society. The widow of Virchow on the same occasion announced that she would make over to the new building the private collections and valuable memorials of Virchow

AT a meeting of the trustees of the Beit memorial fellowships for medical research, the reports by the fellows on their work during the past year, which had been considered by the advisory board, were approved The following is a list of those who were elected to fellowships, the subject of research and the institution in which it is to be carried forward

Thomas Renton Elliott, M D (Cantab), M R C P (Lond) The pathological changes in the suprarenal glands Medical School of University College Hospital

Eric Edwin Atkin, M B (Cantab) A group of toxins with respect to the manner of destruction, mode of neutralization by antibody, and effect of the various modifications upon the animal organism The Bacteriological Laboratory of the London Hospital

Frances Mary Tozer, B Sc (Lond) The presence of sensory fibers in the third, fourth and sixth cranial nerves, their influence upon ocular paralysis in locomotor ataxia and other diseases, and the site of the ganglion cells The Physiological Laboratory of the Liverpool University

Richard Williams Harold Row, B Sc (Lond) The structure, development and functions of the pituitary body in vertebrata King's College, London, the Marine Biological Association's Laboratory, and the Naples Zoological Station

Henry Priestley, M B , Ch M (Sydney) The diphtheroid organisms with regard to their distribution, morphology, cultural characteristics, pathology and relationship to diseased conditions of man and animals The Lister Institute of Preventive Medicine

Frederick Perera Wilson, M D , M Sc (Liverpool) The changes in the lipoids of the tissues produced by syphilis and their relation to hæmolysis and immunity The Biochemical Department of the University of Liverpool.

Arthur Gurney Yates, M D (Edin) The bacteriology of acute rheumatism. The Pathological Department of the University of Sheffield

Annie Homer, D Sc., T.C.D The chemistry and

physiology of tryptophane, the metabolism and chemistry of hæmoglobin in so far as they bear on its production in the animal body, the comparison of normal and pathological tissues as regards their content of intracellular ferments The Physiological and Chemical Laboratories, Cambridge

Frederick James Fitzmaurice Barrington, M B, B S (Lond), F R C S The functions of the male accessory genital glands University College Medical School

John Foster Gaskell, M B, B C (Cantab), M R C P (Lond) The origin of the suprarenal body in the invertebrates and lower vertebrates and the function of chlorogogen cells in invertebrates St Bartholomew's Hospital Medical School

UNIVERSITY AND EDUCATIONAL NEWS

Harvard University has received an additional gift of $100,000 from Mr Adolphus Busch, of St Louis, Mo, towards the erection and maintenance of the Germanic Museum This sum makes a total of $350,000 given to the museum by Mr Busch

It is stated in the *Yale Alumni Weekly* that owing to the lack of room, notwithstanding the great wealth of material, the work of mounting prehistoric animals for public exhibition at Peabody Museum has been temporarily discontinued The development of the resources of the museum must apparently await new building construction This may involve an entirely new site and plant in accordance with the university development on the Hillhouse property The building fund of the institution, according to the last report of the university treasurer, amounted to $173,923

The Harvard University Catalogue shows this year a total enrollment of 4,123 students in the university exclusive of the summer schools, Radcliffe College, and the university extension courses. The total number of students is 77 more than it was at the corresponding period last year. The attendance in the college is 48 less than it was last year, but this decrease is more than offset by gains in the graduate and law schools.

Mr. Clarence T. Johnston has been appointed professor of civil engineering at the University of Michigan, succeeding Professor Emeritus J B Davis, retired on the Carnegie grant Professor Johnson was graduated from the University of Michigan as an engineer in 1895, and received the degree of C E in 1899 He was state engineer of Wyoming during the period in which were formulated the irrigation laws.

At a meeting of the trustees of Princeton University on January 12, 1911, William Gillespie, assistant professor, and George David Birkhoff, preceptor, were made full professors of mathematics Ulric Dahlgren, assistant professor of biology, was made full professor

DISCUSSION AND CORRESPONDENCE

CARELESS CRITICISM

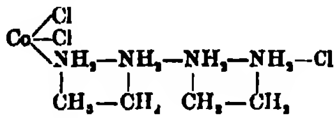
Within the past year a new book has appeared, bearing the title "Recent Advances in Physical and Inorganic Chemistry," by A W Stewart The book has received very favorable comment from the reviewers in various chemical journals, and deservedly so, for the author has selected certain striking lines of advance and has pointed out the chief experimental evidence on which these are based.

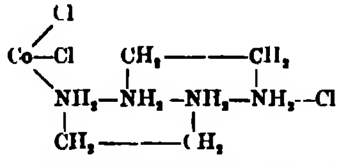
There is one glaring error, however, which seems to have escaped the notice of the reviewers In all of the chapters, except one, the author writes from the standpoint of the record as shown in chemical literature, but in this, the seventh chapter, The Cobaltammines, he departs from his usual conservatism and assumes the rôle of a caustic critic

After a discussion of the various views put forward to explain the structure of these compounds, the author plunges into the Jorgensen-Werner controversy, defending very earnestly Jorgensen's views and criticizing with equal warmth those of Werner. On page 121, following a discussion of the points at issue between Jorgensen and Werner, the author states:

Now, since all these difficulties arise only from the assumption that the ethylene diamine series of compounds are exactly parallel to the tetrammino-compounds, the simplest way out of the difficulty seems to be to abandon any such parallelism. Jörgensen pointed out that in the case of

ethylene diamine, we can imagine two possible arrangements with the cobaltammine molecule—





so that we might attribute the isomerism in these compounds to this difference Now, in the ammonia compounds such an isomerism could not occur, owing to the similarity of all four ammonia groups We should therefore expect to find no isomerism in the case of the ammonia-compounds of the type $[(NH_3)_4CoCl_2]$, *and, as a matter of fact, no such isomers are known, the compound exists in one form only*

And again on page 125, in summarizing the whole controversy, the author states

The question at issue is quite clear Jörgensen points out that if we take the three cases of the dichloro diethylene diammino salts, the dinitrito-tetrammino salts and the dichloro-tetrammino salts, two isomeric series are known in the case of the first two sets, but the dichloro-tetrammino compounds occur in one form only—

$\left[Co{Cl_2 \atop en_2}\right]X$	Occur in two forms
$\left[Co{(NO_2)_2 \atop (NH_3)_4}\right]X$	Occur in two forms
$\left[Co{Cl_2 \atop (NH_3)_4}\right]X$	Only one form known

So that in each case where isomerism is observed there are either two nitro groups or two ethylene diamine molecules Where these are both absent, no isomerism occurs. Werner, on the other hand, maintains that his theory accounts better for the facts, *though he has not been able to produce the two isomeric tetrammino salts which, according to his views, ought to exist* The non production of these salts is specially significant when we consider how easily we can transform one diethylene diamine isomer into the other; evaporation with mineral acids produces one form, from which the other can be regenerated by evaporating with water after making the solution neutral

Briefly, Dr. Stewart contends that Werner's views are untenable as he has not been able to prepare the isomeric modification of dichloro-tetrammino cobaltic chloride This is the crowning argument with which the chapter is closed

Unfortunately for the argument, Werner published in 1907 in so accessible a journal as the *Berichte der Deutschen Chemischen Gesellschaft*, Vol 40, p 4817, a full account of the discovery, the method of preparation, and the properties of this second and isomeric modification of dichloro-tetrammino-cobaltic chloride This was no accidental discovery, nor the result of haphazard experiment, but a logical consequence of the extension of Werner's views to the complicated poly-nucleal compounds, a field brilliantly developed by Werner during the past twelve years, but not mentioned in the chapter on Cobaltammines

The critic can not afford to be careless in keeping up with the literature of a subject The plea of recent publication of Werner's work on this compound can not be put forward, as Dr Stewart has included in this chapter the still later (1908) published views of Ramsay and of Friend, indeed, the date of his preface, September, 1909, shows that the manuscript was in hand two years after Werner's announcement in the *Berichte* of his success in preparing the isomeric modification of dichloro-tetrammino-cobaltic chloride.

SCIENTIFIC BOOKS

The Differentiation and Specificity of Corresponding Proteins and Other Vital Substances in Relation to Biological Classification and Organic Evolution The Crystallography of Hemoglobins By E. T REICHERT and A. P BROWN Washington, D C, published by the Carnegie Institution of Washington. 1909.

This is an important and very interesting work, the combined production of a physiologist and a crystallographer This review will be restricted to a consideration of some

of the results that are of interest to the biologist[1]

Hemoglobin, the coloring matter of the blood, which in vertebrates is contained in the blood corpuscles, and which is a combination of a proteid, the globin, with the coloring matter proper, the hematin, can more or less readily be obtained in the form of crystals Many investigators have studied the conditions under which these crystals form and some of their characters in different species of animals The work of Reichert and Brown is, however, by far the most thorough and extensive investigation which has so far been published, and on the basis of their careful studies the authors arrive at broad biological conclusions, which will be of great interest to a wide circle of scientists

The results obtained leave no doubt that the crystals of the hemoglobin of different species are not identical, and the work, moreover, raises problems which have not been considered by previous investigators The authors show that not only do the crystals of different species of animals differ, but also that this difference is a graded one, corresponding to the position which the various species occupy in the zoological system As the crystals of nearly related species resemble each other more closely than those of more distantly related species, the character of the crystals permits us to decide, within certain limits, how nearly related to each other animals are Furthermore, inasmuch as crystallographic characters are the expression of chemical constitution, we may conclude that the hemoglobin of various species shows gradations in its chemical constitution corresponding to the close or more distant relationship of the species. We may also assume that gradations parallel to those shown by the crystals of hemoglobin exist in the other proteins Thus we have a means of testing by crystallography the classification of animals, which at present is based almost entirely on morphological characters

The comparative study of the crystals of hemoglobin by the authors confirms, on the whole, the correctness of the classification generally adopted by zoologists, but there are certain instances in which the authors believe that their findings suggest a revision To cite two examples (1) It is ordinarily assumed that the white rat is an albino of the black rat, the crystallographic examination of the various species of rats shows, however, that the white rat is closely related to the brown or Norway rat, while the black, or Alexandrine rats are more nearly related to each other (2) The crystals of hemoglobin from the brown bat show a considerable resemblance to the crystals of hemoglobin of Papio, which belongs to the primates This agrees with the view of some zoologists, according to which the bats are related to the primates, although, on the other hand, the crystals of the fruit bat do not show this resemblance to those of Papio

On the whole, the main results of Reichert and Brown harmonize very well with our general biological conceptions of the graded relationship of differences in the chemical constitution of proteid substances, a conception mainly founded upon the results obtained through the application of the so-called biological tests (precipitin, anaphylaxis, complement fixation reactions), and especially are the conclusions of these authors in good agreement with the results of experiments in which watery extracts of erythrocytes have been used as an antigen and in which the erythroprecipitins obtained were shown to be specific for the antigens of the various species which had been employed These studies have definitely proved that the proteid substances from

[1] The reviewer consulted two experts in crystallography in regard to the soundness of the crystallographic basis of the work, and he may be permitted to cite here a few sentences

Professor Edward H Kraus, of the University of Michigan, states "From the crystallographic standpoint, Professor A P Brown has done a remarkable piece of work which is deserving of highest credit"

Dr J E Pogue, of the Smithsonian Institution "The actual crystallographic and optical details are apparently determined with skill and accuracy The photomicrographs are excellent, and the line drawings good"

the various organs of a certain species have in common a "species" group that is characteristic for one species and differentiates it from nearly related species. By these "biological" methods it had also been found that the constitution of these groups of proteid is more similar in nearly related than in more distantly related species, and several investigators, especially Osborne and Abderhalden, had previously taken up the problem of the chemical characterization of species differences by the methods of analytical chemistry.

The work of Reichert and Brown differs, however, in some important aspects from the previous investigations (differentiation by biological tests). While in the latter the substances compared with each other were usually chemically not well defined, Reichert and Brown worked with a definite chemical substance, the hemoglobin. By the method of crystallization it is, moreover, possible to detect differences in chemical constitution which are at present not accessible to ordinary chemical analysis and in this way it is possible to differentiate between species so nearly related, that even by means of the so-called biological tests the differentiation is accomplished only with great difficulty.

After a study of Reichert and Brown's work little doubt is left in the mind of the reader in regard to the usually close relationship of the crystals of the species belonging to one genus or occasionally even of the great similarity of the crystals of two nearly related genera, it seems, however, not yet established that a *general* parallelism exists between the true relationship of the various orders and classes of animals and the character of their hemoglobin crystals.

It might furthermore be questioned in those cases in which a divergence seems to exist between the ordinary classification and the results of the crystallographic studies, whether the latter should be accepted unhesitatingly. It rather seems that in such cases of doubt a comparative study by the crystallographic, and by the so-called biological tests should be used to confirm the former. This would be especially desirable in view of the great lability of the hemoglobin molecule which the authors themselves repeatedly emphasize. We might, *e. g.*, question whether the different kinds of crystals of oxyhemoglobin found occasionally in the same blood might not be the result of certain secondary chemical changes in the hemoglobin molecule. In this connection it is of interest that in a recent publication Offringa states, that if the crystals of hemoglobin of the horse are prepared without the addition of any salt (Reichert and Brown made use of oxalates in their work), only one kind of crystals is obtained.

In the work of Reichert and Brown, as well as in the more recent literature generally, the term "specific" is frequently encountered, and it is apparently supposed to have a definite biochemical meaning. A more searching analysis, however, reveals the fact that this term includes three different relationships between substances, and a clear distinction between these appears to be very desirable. Several years ago the reviewer described a class of substances which he designated as specifically adapted, these are substances coexisting in the same organism and showing functional relations to each other. In other cases the term "specific" merely indicates a character of a certain species by which it differs from other species, without any parallelism existing between this characteristic and the zoological classification. In a third class of specific characters such a relationship exists, and this third kind of specificity might appropriately be called "generic specificity." With the latter, we have principally to deal in the work of Reichert and Brown.

The work of these authors includes also a consideration of the general characters of hemoglobins as well as a summary of other differences which have been found in the blood of different species by previous investigators. With some opinions expressed in this part of the book issue might, perhaps, be taken, as for instance, in regard to the low estimate of the physiological importance of iron as a constituent of hemoglobin; a view

against which especially the recent investigations of W. Manchot might be cited.

The fine reproduction of 100 plates of beautiful microphotographs of hemoglobin crystals of various species of animals is especially noteworthy.

LEO LOEB

A Monograph of the Culicidæ or Mosquitoes. Volume 5. By FRED. V. THEOBALD. British Museum (Natural History). London. 1910. Pp. xvi + 646. 261 text figures, 6 plates.

The author has assembled in this volume descriptions of many recently erected genera and species, characterized thirteen genera and eighty species as new, supplied keys for the separation of the genera and a very large proportion of the described species and, in addition, gives observations or references to practically all other genera and species. This latter makes the fifth volume practically a systematic index to the preceding four volumes and will greatly facilitate future studies in this group.

The modified classification proposed by Lutz and outlined in volume four has been closely followed. We regret to note that the tables for the recognition of the genera are based largely upon scale structure, a method of separation which has found comparatively slight favor in America, though we can not ignore the author's statement, especially in view of his wide experience with these insects from all parts of the world, that separation in this manner is comparatively easy, as evidenced by the number of correctly named collections received at the British Museum. The monograph, as a whole, is weak from a structural and biological standpoint, and necessarily so in many instances, especially in the case of forms received from distant countries where methods of collection and preservation are far from ideal. The study of the imago must, as a rule, precede biological investigations, and it is therefore not surprising that the immature stages have received comparatively little attention in this work. We sympathize strongly with the author in his declining to recognize genera and species based solely upon larval characters, despite the fact that such procedure is not sanctioned by the International Code of Zoological Nomenclature. It is true that good characters are found in the larvæ of this group, and that in some instances species are more readily separated in the larval than in the adult form. Nevertheless, our classification of the family is based upon the imago, and confusion is bound to result from the employment of a double standard, though technically allowable, it is in this group questionable procedure.

There are important problems in synonymy which should be settled in the near future for the purpose of avoiding confusion if for no other reason. The author declines to accept the broad delimitation of Aedes, recently proposed in this country, and, as a consequence, the nomenclature used by a number of American workers differs widely from that employed in the volume under consideration. Personally, without having made special study of the problems involved, we question the wisdom of attempting to unite under one name such diversified forms. On the other hand, a number of generic names have been allowed to stand as valid in this work which will probably fall as synonyms because of the absence of satisfactory characters. These and similar questions can be settled only by an exhaustive comparative study of the characters presented by the immature stages as well as those of the adult. The key to the solution of many of these problems will be found in the unrivaled collections from all parts of the world, now assembled in the British Museum of Natural History.

The diversity and size of this group is indicated by the eight subfamilies recognized (excluding the Corethridæ), comprising some 146 genera and 899 species, a large majority of these being valid. The world owes Professor Theobald a debt of gratitude for assembling, carefully describing and arranging this immense amount of material, among which are included some of the most dangerous insect enemies of man. Prior to this study, our knowledge of the Culicidæ was

little better than chaotic, many species being unknown or else grouped under a specific name mostly noteworthy because of its comprehensiveness We think all will agree that Professor Theobald has done a large amount of valuable pioneer work, though we may not adopt all of his taxonomic views The British Museum is to be congratulated upon having published such an admirable work, of which the volume under consideration forms only a part, consisting of five good-sized volumes, illustrated by a large series of figures, there being over 1,200 text illustrations and 88 magnificent plates, and characterizing practically all the known species in this important family It is perhaps needless to add that this monograph on the Culicidæ, possibly not even yet completed, must be the major foundation for all subsequent studies in this group and therefore nearly indispensable to the systematist

E P FELT

SPECIAL ARTICLES

NEW PHENOMENA OF ELECTRICAL DISCHARGE

AT a meeting of the Academy of Science of St Louis on December 5, the writer gave further results of work on electrical discharge It had been previously shown that oscillations of widely varying frequency, attended by musical tones, could be brought about, by means of small spark gaps of variable length, in the lines leading from the terminals of an influence machine to the main gap across which the discharge is to pass In a former paper it had been suggested that the striæ in a vacuum tube were in the nature of waves in an organ pipe

These results suggested the idea of imposing resonance vibrations in a column of air contained in a glass tube, which also contained terminals from the influence machine. The air vibrations were produced by means of a blast of air from a pressure tank, which was directed across the mouth of another tube. It has been found that with very careful adjustments, the electric discharge across a small gap in the glass tube could be affected in a marked way by the impressed sound waves A luminous discharge was apparently converted into a dark discharge

The line within the tube containing this gap was in multiple with another line containing an adjustable gap This system was in the positive side of a circuit which contained a long discharge gap Placed transversely in this gap was an insulated sheet of copper, which served to prevent disruptive discharges Attempts are now being made to cause an organ pipe to sound a musical tone by means of periodically varying electrical stresses within the air-column The response of the air-column is not as marked as when the vibrations are produced in the ordinary way Some effects have however been secured, and there is every reason to believe that the attempt will meet with success These results can only be considered as preliminary

Several friends have suggested that the term drainage column as applied to the positive or luminous end of a discharge, was another name for an ionized mass of air If we say that air is ionized by X-rays passing through it, this term does not represent the conditions at either terminal of an influence machine

In a mass of air ionized by X-rays, the average charge of a molecule is the normal charge Those which have a greater than normal charge mingle with those which have a less than normal charge Such a mass of air will respond to the demands of an electrometer placed within it, whether its leaves have a greater or a less than normal charge The supercharged molecules will deliver the excess to those whom they have robbed, or to any others which may be in a like condition A similar statement may be made concerning the molecules which have less than the normal charge. But such a mass of air is not a drainage column It is in a condition which promotes the formation of a drainage column, if the terminals of some "source" of electricity like an influence machine are placed within the ionized mass of air This mass of air is then made a part of the conducting circuit, by the starting of the machine into action The fact that it behaves differently from the rest of the circuit is incidental to the fact

that it is in gaseous condition. The apparent discharge into the air from the positive terminal was shown by phenomena described in my paper of February 18, 1910,[1] to be an inflow of negative electricity to that terminal. The electric fluid is thus drained from a column of air which begins at the positive terminal and extends towards the negative or compression terminal. After this drainage has been brought about, the air within this column is in a very different condition from that of air ionized by X-rays. The average charge per molecule of air is then less than the normal amount. By placing an insulated sheet of copper between the terminals, the drainage or conduction column is prevented from reaching the mass of supercharged air in front of the negative terminal. Loud disruptive discharges will pass when the plate is removed, and they cease at once when the plate is placed midway between the terminals. On moving the copper plate nearly to the negative glow, the drainage column follows it, and a torrent of sparks will pass.

The so-called positive ions do not emerge from the wire at the positive terminal, and they do not enter the wire at the negative terminal. When this air is nearly all removed from the discharge gap, as is done in the Crookes tube, the cathode discharge still continues. The drainage column has disappeared at the anode. When the air is partially removed, thus increasing the mean free path, the drainage column may have a great length, and it follows all of the windings and bends of the tube. It would not do this if it were an outward discharge like that from the negative terminal.

This drainage column constitutes the canal rays, in a tube where the gas has been partly exhausted, so that the mean free path has been increased. In a paper to be published by the Academy of Science of St. Louis, phenomena of canal rays in air of ordinary pressure will be presented, in connection with phenomena involved in vibrations imposed upon the air column.

[1] *Trans. Acad. of Sc. of St. Louis*, Vol. XIX, No. 1, Plates II to VIII.

If any trace of a positive fluid capable of moving through a wire as an electric current must move could be found, and if the two-fluid theory could furnish an adequate and rational explanation of these and other phenomena, there would be no objection to its use in an exposition of the subject, as has been the custom heretofore.

In 1895 the writer showed that the velocity of flow of the electric fluid in a pumping service then discussed, must be very great. Imagine two spheres having radii equal to that of the earth. Suppose electricity to be pumped from one into the other, until their difference in potential is 50 volts. Connect them by means of a 50-volt one-ampere lamp. It would begin to glow with normal brightness. In order to keep the voltage constant the radii of the two spheres must be diminished with a uniform velocity of more than half the velocity of light. This store of electricity would maintain this lamp at normal candle power for 0.035 second. The operation must be repeated 28 times a second. The time for one stroke of the piston is in seconds, $t = Rr$, where r is the radius of the spheres in cm. and R is the resistance of the lamp in electrostatic units. If the sphere from which the electric fluid were pumped, by some adequate means, had an infinite capacity, the other sphere must then be charged to a potential of 50 volts, and the above results would remain unchanged. The surface of the charged sphere would then be the piston of an electrical pump, and its velocity would be as given above. All of this store of electricity must pass through the lamp in 0.035 second.

We may learn much about the constitution of matter by a study of what are called the positive ions when an electric discharge is passed through a column of gas. But nothing has yet been learned to indicate that these ions play any part in a lamp circuit, except that they then constitute the solid conductor.

Wheatstone's work now shows us that when half a mile of copper wire is placed centrally in the spark gap, we have compression and rarefaction waves in Franklin's fluid, which meet at or near the middle of the wire. The

positive ions are in some way linked together, and transmit Thomson's corpuscles with immense velocity. There is a certain amount of shaking up involved in this transfer. It is the Joule effect. The positive ions remain at rest, and there are, therefore, no canal rays. When this wire is removed from the spark gap, the gas molecules receive the same compression and rarefaction waves, if the man who turns the crank of the machine continues his work. At the negative terminal the air molecules are loaded with the corpuscles, in the region of negative glow. They are then urged by convection as carriers, across the Faraday dark space. At the positive terminal the corpuscles pass from the gas into the metal conductor by a rarefaction or drainage process. Photographic plates reproduced in former papers[2] show that the drainage lines begin at the positive terminal. In this drainage column the carriers of the discharge move in a direction opposite to that in which the discharge is being urged. Cakes of ice floating on water would behave in a similar way, if a runner should jump from one to another, although the mechanism would be different. Nevertheless, such behavior of cakes of ice appears to be related to the athletics of the foot race, in somewhat the same way that positive ions in a gas are related to the flow of electricity in a power circuit.

FRANCIS E. NIPHER

JOINT MEETING OF MATHEMATICIANS AND ENGINEERS AT MINNEAPOLIS

THREE years ago in connection with the convocation of the American Association for the Advancement of Science in Chicago, a joint meeting of mathematicians and engineers was arranged through a committee of the Chicago Section of the American Mathematical Society. This meeting aroused much interest and resulted in the appointment of a committee of twenty, under the chairmanship of Professor E. V. Huntington, of Harvard University, to consider the whole question of the teaching of mathematics to students of engineering in this country, and to report its recommendations to the Society for the Promotion of Engineering Education at its summer meeting to be held at Madison, Wis., in June, 1910. This committee was constituted as follows: Philip R. Alger, professor of mathematics, U. S. Navy, Annapolis, Md.; Donald F. Campbell, professor of mathematics, Armour Institute of Technology, Chicago, Ill.; Edmund A. Engler, president of the Worcester Polytechnic Institute, Worcester, Mass.; Charles N. Haskins, assistant professor of mathematics, Dartmouth College, Hanover, N. H.; Charles S. Howe, president, Case School of Applied Science Cleveland, Ohio; Emil Kuichling, consulting civil engineer, New York City; William T. Magruder, professor of mechanical engineering, Ohio State University, Columbus, Ohio; Ralph Modjeski, civil engineer, Chicago, Ill.; William F. Osgood, professor of mathematics, Harvard University, Cambridge, Mass.; Charles S. Slichter, consulting engineer of the U. S. Reclamation Service, professor of applied mathematics, University of Wisconsin, Madison, Wis.; Charles P. Steinmetz, consulting engineer of the General Electric Company, professor of electrical engineering, Union University, Schenectady, N. Y.; George F. Swain, consulting engineer, professor of civil engineering, Harvard University, Cambridge, Mass.; Edgar J. Townsend, dean of the College of Science and professor of mathematics, University of Illinois, Urbana, Ill.; Frederick E. Turneaure, dean of the College of Mechanics and Engineering, University of Wisconsin, Madison, Wis.; Clarence A. Waldo, head professor of mathematics, Washington University, St. Louis, Mo.; Gardner S. Williams, consulting engineer, professor of civil, hydraulic and sanitary engineering, University of Michigan, Ann Arbor, Mich.; Calvin M. Woodward, dean of the School of Engineering and Architecture and professor of mathematics and applied mechanics, Washington University, St. Louis, Mo.; Robert S. Woodward, president of the Carnegie Institution of Washington, Washington, D. C.; Alexander Ziwet, professor of mathematics, University of Michigan, Ann Arbor, Mich.

In the early part of its investigation the committee collected a large amount of information in regard to the present status of mathematical instruction for engineering students. Since that time, however, a much more inclusive inquiry has been undertaken by the International Commission on the Teaching of Mathematics, of which the American Commissioners are Professors D. E. Smith, J. W. A. Young and W. F. Osgood. In

[2] *Trans. Acad. of Sc. of St. Louis*, XIX., Nos. 1 and 4, Plates X., B, XX., A, B and C, and XXI., A.

order to avoid unnecessary duplication, this committee voted to turn over all the results of its own inquiry in this field to the larger commission, to be worked up in accordance with the general scheme adopted by that commission, and to be incorporated in their report This material is therefore not included in the present report

Aside from the collection of data, Professor Huntington's committee decided that the most important need at the present time is a series of synoptical text books, which shall present (1) the fundamental principles of the science, in compact form, and (2) a classified and graded collection of problems (which would naturally be subject to continual change and expansion). It is their hope that the Minneapolis report, which is confined to the first part of the desired text-book, will stimulate throughout the country practical contributions toward the second

Copies of these syllabi were distributed among the hundred or more engineers, physicists and mathematicians who joined in a good fellowship dinner on the evening preceding the presentation of the report Additional copies may be had upon request from the chairman The following quotations from the preface will indicate its scope and purpose

"The object of this report is to present a synopsis of those fundamental principles and methods of mathematics which, in the opinion of the committee, should constitute the minimum mathematical equipment of the student of engineering

"It is hoped that this report may be serviceable in two ways first, to the teacher, as an indication of where the emphasis should be laid, and secondly, to the student, as a syllabus of facts and methods which are to be his working tools It does not include data for which the student would properly refer to an engineer's hand book, it includes rather just those things for which he ought never to be obliged to refer to any book—the things which he should have constantly at his fingers' ends

"The teacher of mathematics should see to it that at least these facts are perfectly familiar to all his students, so that the professor of engineering may presuppose, with confidence, at least this much mathematical knowledge on the part of his students On the other hand, if the professor of engineering needs to use, at any point, more advanced mathematical methods than those here mentioned, he should be careful to explain them to his class

"The defects in the mathematical training of the student of engineering appear to be largely in knowledge and grasp of fundamental principles, and the constant effort of the teacher should be to ground the student thoroughly in these fundamentals, which are too often lost sight of in a mass of details

"The committee has not found it possible to propose a detailed course of study The order in which those topics should be taken up must be left largely to the discretion of the individual teacher The committee is firmly of the opinion, however, that whatever order is adopted, the principal part of the course should be problems worked by the students, and that all these problems should be solved on the basis of a small number of fundamental principles and methods, such as are here suggested"

The report was freely discussed and frankly criticized by a large number of speakers including the following Professors E J Wilczynski, University of Chicago, A G Hall, University of Michigan; E H Comstock, School of Mines of the University of Minnesota, G A Miller, University of Illinois, A. E Haynes, College of Engineering of the University of Minnesota, E F Nichols, president of Dartmouth College, T F Holgate, dean of Northwestern University, Alexander Ziwet, University of Michigan; E R Maurer, College of Engineering of the University of Wisconsin, Henry Crew, department of physics of Northwestern University, H E Slaught, University of Chicago, B L Newkirk, University of Minnesota, E. F Chandler, University of North Dakota, J J Flather, head of mechanical engineering, University of Minnesota, and L E Dickson, University of Chicago, chairman of the meeting Also numerous discussions in writing were received by the chairman or through the secretary, including one from President R. S Woodward, of the Carnegie Institution of Washington, one from Professor A E Haynes, of the University of Minnesota, and one from William Kent, president of the Technical Literature Company of New York

The discussion finally led to the following resolution, which was unanimously adopted·

Resolved, that this body tenders hearty thanks to Professor Huntington for the great interest which he has shown in this work and the untiring service which he has given to it, that we commend the work of the entire committee for the preparation of a report which it is believed must operate for betterment along the lines of its

recommendations, and while not prepared to approve in all respects the details, especially in the syllabus on dynamics, as shown by the full and free discussion at this meeting, yet we heartily endorse the spirit of the report and thank the officers of the Society for the Promotion of Engineering Education, who have shown their friendly cooperation in offering to publish these syllabi in their official *Bulletin*, for the purpose of drawing out further criticisms and suggestions either in printed papers or in written communications to the chairman of the committee

The further report of this committee is to be presented at the next meeting of the Society for the Promotion of Engineering Education in June, 1911 The present meeting was organized, as was the original meeting in Chicago in 1907, by the Chicago Section of the American Mathematical Society

Other papers read before the Chicago Section at the Minneapolis meetings, aside from those in astronomy for which joint sessions were held with Section A, were as follows

"On the Use of the Co-sets of a Group," Professor G A. Miller, University of Illinois

"Congruencial Theory of Functions of Several Variables," Professor L E Dickson, University of Chicago

"Generalizations of Theorems on Linear Algebras," Professor L E Dickson

"On Primitive Roots of Ideals," Professor Jacob Westlund, Purdue University.

"The Problem of Defining the Set of Real Numbers," Dr A B Frizell University of Kansas

"A Historical Note on the Newton Raphson Method of Approximations," Professor Florian Cajori, Colorado College

"One Parameter Families and Nets of Plane Curves," Professor E J Wilczynski, University of Chicago

"Circular Numbers for a Plane Curve," Dr Horace T Burgess, University of Wisconsin

"Rational Anharmonic Curves upon a Quadric," Dr. Horace T Burgess

"The Applications of Matrices to Cubic Forms," Dr Horace T Burgess

"Envelopes of One Parameter Families of Plane Curves," Professor Walter J Risley, James Millikin University, and Professor W E MacDonald, Canton College, China

"A Reduction of Two Power Series in Many Variables to Two Equivalent Polynomials," Dr. W D MacMillan, University of Chicago.

"The Path of Light in a Medium Homogeneous in Concentric Spherical Layers," Dr Harris F MacNeish, Yale University

"The Curves of Equal Action for Elliptical Coordinates," Professor Kurt Laves, University of Chicago

"Robert of Chester's Translation of the Algebra of Al Khowarazmi," Professor L C. Karpinski, University of Michigan

"Hindu Numerals in the Kitab al Fihrist," Professor L C Karpinski.

"Ruled Surfaces and Planed Hypersurfaces in Four-Dimensional Space," Dr. Arthur Ranum, Cornell University

"Transformation Groups and Substitutions of an Infinite Degree," Dr L I. Neikirk, University of Illinois

"Use of Quaternions in Differential Geometry," Professor J B Shaw, University of Illinois

"On Plane Quintic Curves," Dr H L Slobin, University of Minnesota

"On the Construction of a Certain Class of Periodic Solutions of the Problem of Three Bodies," Professor F R Moulton, University of Chicago

"Curves on Quintic Scrolls," Professor Frank B Williams, Clark College

The next meeting of the Chicago Section will be in Chicago on Friday and Saturday, April 28 and 29, 1911

H E SLAUGHT,
Secretary of the Section

THE AMERICAN PHYTOPATHOLOGICAL SOCIETY

THE second annual meeting of the American Phytopathological Society was held in affiliation with the American Association for the Advancement of Science at Minneapolis, Minn, December 28–30, 1910. The attendance was not as large as at the Boston meeting, but an excellent program of twenty-eight papers was presented A joint session with Section G of the American Association and the Botanical Society of America was held at the Minnesota Agricultural College on Thursday, December 29, and other sessions at the University.

The society wishes to express its appreciation and gratitude to the local committee and especially to Dr. F. E Clements for the excellent rooms and facilities provided

The constitution of the society, drafted and approved by the council, was adopted The following officers were elected

President—Professor A D. Selby, Ohio Agricultural Experiment Station, Wooster, Ohio

Vice-president—Dr R. A Harper, University of Wisconsin, Madison, Wis

Secretary-treasurer—Dr C L Shear, U S. Department of Agriculture

Members of Council—Dr G P Clinton, Connecticut Agricultural Experiment Station, New Haven, Conn one year, Dr Erwin F. Smith, U S Department of Agriculture, two years The two *ex officio* members of the council are Dr F L Stevens, retiring president, and Dr L R. Jones, chairman of board of editors of *Phytopathology*

The following editorial board for the new journal *Phytopathology* was elected

Editors—L R Jones C L Shear, H H. Whetzel

Associate Editors—G P Clinton, E M Freeman, H T Gussow, F D Heald, Haven Metcalf, W A Orton, W M Scott, A D. Selby, Erwin F Smith, Ralph E Smith, F L Stevens and Roland Thaxter, with Donald Reddick as business manager.

The society elected thirty seven new members The next annual meeting will be held at Washington, D C, in affiliation with the American Association for the Advancement of Science.

The following committee on legislation concerning plant diseases was appointed: Mel T Cook, F L. Stevens, F C Stewart, H T. Gussow and A D Selby, *ex officio* The committee on names of plant diseases presented a report and was continued

The following papers were presented.

"Tannin in Relation to the Enzymes of the Plant Cell,' Mel T Cook

"The Persistence of *Bacillus amylovorus* in Pruned Apple Twigs," H. R. Fulton (Read by C L Shear)

"The Industrial Fellowship in Plant Pathology," H. H Whetzel.

"*Sclerotium rhizoides* Auersw. on *Calamagrostis*," A. B Stout

"The Relation of Temperature to Spore Germination and Infection with *Cystopus*," I. E. Melhus

"The Rusts of White and Red Clover," Frank D. Kern. (Read by title)

"Black Leg or *Phoma* Wilt of Cabbage, a New Trouble to the United States caused by *Phoma oleracea* Sacc," Thos. F Manns (Read by A. D. Selby)

"The *Fusarium* Blight and Rot of Potato; Field Experiments in Prevention," Thos. F. Manns (Read by A. D. Selby.)

"The White Pine Blister Rust," Perley Spaulding (Read by Haven Metcalf)

"A Study of some Anthracnoses and their Relations to a Sweet Pea Disease," J J Taubenhaus (Read by Mel T Cook)

"The Ascogenous Form of the Fungus causing Dead-arm of the Grape," C L Shear.

"Further Notes on the Bark Disease of the Chestnut," Haven Metcalf and J Franklin Collins

"Necrosis and Crown Gall Diseases of Grapes in New York," D Reddick.

"Peach Leaf curl in Nursery Stock," V B. Stewart (Read by D Reddick)

"Some Laboratory and Field Studies on Fungicidal Values," E Wallace, F M Blodgett and Lex R Hesler (Read by H H. Whetzel)

"Varietal Resistance of Beans to Anthracnose," M. F Barrus (Read by H H Whetzel)

"A Preliminary Report upon the Effects of Arsenical Compounds upon Apple Trees," B D. Swingle (Read by C. L Shear)

"Results of Cotton Anthracnose Work for 1910," H W. Barre.

"Notes on some Diseases of Trees in our National Forests, II," George Grant Hedgcock. (Read by title)

"A New Fruit Spot of Apple," W M. Scott. (Read by C L Shear)

"Contribution to our Knowledge of the Mine Fungi of the United States," C J. Humphrey

"A Bacterial Disease of Bananas and Plantains," James Birch Rorer. (Read by Erwin F. Smith)

"The Leaf Spot of Sugar Beets," C. O. Townsend (Read by title.)

"Notes on Hypertrophied Structures," Mel T. Cook

"The Grand Rapids Tomato Disease," Erwin F. Smith.

"Crown Gall of Plants," Erwin F. Smith.

"Cereal Smut Spore Germination," E. C. Stakman. (Read by title.)

"Alfalfa Rust and Timothy Rust in Iowa," L. H. Pammel.

Abstracts of these papers will appear in the April number of *Phytopathology*, the new journal of the society, and some of the papers will be published later in the same journal.

C. L SHEAR,
Secretary

SOCIETIES AND ACADEMIES

THE NEW YORK ACADEMY OF SCIENCES
SECTION OF BIOLOGY

A REGULAR meeting of the section of biology was held at the American Museum of Natural History, November 14, 1910. In the absence of Chairman Charles B. Davenport, Dr. Alexander Petrunkevitch presided. The following papers were read:

The Effects of Exposure on the Gill Filaments of Fishes: RAYMOND C. OSBURN.

Salmonoid fishes hatched and reared under artificial conditions frequently show a malformation of one or both of the gill covers, as a result of which the gill filaments are exposed. This condition has been observed in many hatcheries, the percentages sometimes being as high as twenty per cent. The deformity in the fishes studied is produced by the rolling in of the operculum. 486 yearling silver salmon reared in the New York Aquarium were examined with the following results: normal, 397; right opercle short, 44; left opercle short, 27; both opercles short, 18; percentage of abnormality, 18.31.

On examination under the microscope the exposed filaments are found to be quite abnormal. The epithelium, instead of being composed of thin flattened cells, is greatly thickened, consisting of cuboid or columnar cells, and in some cases several layers of the cells are found. The secondary laminæ, in which respiration for the most part takes place, are often reduced or wanting and the blood capillaries are not fully developed.

The hypertrophy of the epithelium, while it undoubtedly protects the filaments against abrasion, must at the same time seriously interfere with their function in respiration. The cause of the deformity of the opercle is unknown. Fish culturists have noted its appearance very early in fry, but whether it is congenital or is induced by crowding or by other untoward conditions in the hatching trays, further observations must decide.

Courtship in Tarantulas: ALEXANDER PETRUNKEVITCH.

The instincts of the male tarantula change suddenly at the period of maturity. From a creature with domestic habits he develops into a vagabond. Disregarding personal danger he constructs a sperm-web into which he throws out his sperm and pumps it then into both of his palpi. In the search for the female he is entirely dependent upon his sense of touch, his sense of sight being entirely inadequate for the purpose. The courtship is therefore very short and consists in beating the female with his front legs. The danger of being hit by the fangs of the excited female is prevented by catching them with the hooks on the front legs. The coitus lasts not longer than one half minute, after which the spiders cautiously separate. A few weeks later the males die apparently a natural death.

AT the regular meeting of this section held at the American Museum, December 12, 1910, Mr. Roy W. Miner presiding, the following papers were read:

The Effect of Changes in Water Density on the Blood of Fishes: G. G. SCOTT.

When salt water fishes are placed in fresh water they gain in weight. Investigation of the blood shows that there is a decrease in number of corpuscles per cubic millimeter and that the specific gravity of the blood decreases.

Tests with the Beckmann apparatus show that the freezing point of the blood of such fishes is higher than that of normal blood. If the fishes are placed in a solution of sea water plus sea salt, the corpuscle count is increased, the specific gravity of the blood is greater and the freezing point of the blood is depressed. A chemical examination of the chlorides of the blood of normal fish as compared with the chlorides of fishes kept in fresh water, shows that the loss of chlorides in case of the fishes experimented on is greater than the mere dilution of the blood by the endosmosis of water would account for. Hence, under the abnormal conditions to which the fish is subjected the gills become permeable to salts. The osmotic pressure of the blood is thus profoundly changed. That these changes reach the tissues is indicated by investigations now going on. The death of the fish which usually accompanies such sudden transitions as are employed in these experiments is possibly caused by conditions set up similar to those in such diseases as dropsy. It is hoped that further investigations now being carried on will clear up this question.

Marine Ecology and its Representation in a Museum: ROY W. MINER.

The speaker described the chief associations of marine animals to be found between the tides or just below the lower tide limits along the north Atlantic coast, with especial reference to the annulates and mollusca and the fauna of wharf piles in the Woods Hole region and the north shore of Long Island. The methods of collecting were then briefly outlined, and the chief steps for preserving data, observations, etc., for museum ecological groups were mentioned. The speaker then discussed the problems connected with con-

structing and installing groups and models of invertebrates in a museum. Colored slides were shown both of the living invertebrates and of their habitats, and also of the models and groups in course of construction and as completed at the American Museum The speaker concluded by exhibiting two sketch-models prepared under his direction by Messrs Mataush and Shimotori, of the museum staff, as preliminary studies for the annulate and pile fauna groups which are in course of construction in the American Museum.

Exhibition of Models of Membracidæ. IGNAZ MATAUSCH

The speaker exhibited a series of six enlarged models in wax which he had prepared for the American Museum of Natural History, as well as a series of twenty-three colored drawings and a collection of typical specimens which had been sent him by Professor F Silvestri, of Portici, Italy.

The Membracidæ, or tree-hoppers, are among the most interesting of insects Very little is yet known concerning their *life histories*, a subject to which the speaker said he had devoted considerable attention They are remarkable for their extraordinary variation in the form of the prothorax In order to make an enlarged model it is necessary to dismember the insect and to prepare drawings of the different parts to a selected scale The separate parts are then copied in clay, plaster molds are then prepared and casts made in wax These are then finished, the details put in, and the whole put together and colored

L. HUSSAKOF,
Secretary

AMERICAN MUSEUM OF NATURAL HISTORY

THE AMERICAN CHEMICAL SOCIETY

NEW YORK SECTION

THE fourth regular meeting of the session of 1910–11 was held at the Chemists' Club on January 6

The Nichols medal, awarded annually for the best paper read before the section, was presented to M A Rosanoff and C W Easley for their paper "On the Partial Vapor Pressures of Binary Mixtures" Professor W D Bancroft, president of the society, made the presentation and Professor Rosanoff accepted the medal on behalf of himself and Professor Easley

In receiving the medal, Professor Rosanoff said

"*Mr. Chairman, Dr. Bancroft, Dr. Nichols, Gentlemen*: I thank you all, on behalf of Dr. Easley and myself, for the great honor you are this evening bestowing upon us. It will be an ever present support against discouragement in the research struggle to which, I hope and believe, my life will be devoted to the end.

"Much of the honor adjudged to us is due—it is a pleasure to admit—to Clark University, whose unexampled freedom, and liberalism, and Nietzschean belief in the future, form an ideal atmosphere for scientific research.

"Gentlemen, Ostwald prophesies that the center of gravity of science is bound to move from Europe across the Atlantic This chemical society, a body devoted mainly to the furthering and encouragement of chemical research, can do more than any other group of men, more even than the universities, toward hastening that migration, which will open a remarkable era in American history. Every honor conferred by the society on the basis of research must stimulate that migration and will, therefore, rebound to the society itself"

Mr T. J Parker gave an account of the Minneapolis meeting of the American Chemical Society.

Dr W C Moore read a paper by Professor H N McCoy and himself on "Organic Amalgams"

Professor Robert Kennedy Duncan addressed the section "On the Relation between Chemistry and Industry in America" Formal discussion of the subject followed by M C Whitaker, L. H. Baekeland and Allen Rogers

C M JOYCE,
Secretary

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 476th regular and 31st annual meeting was held at the hall of the Cosmos Club, December 10, 1910, with President T S. Palmer in the chair

Reports of the secretary and treasurer were read and approved. Four new members were elected

The following officers for 1911 were elected

President—David White

Vice-presidents—W. P. Hay, E. W Nelson, J. N Rose and Edw. L. Greene

Recording Secretary—D. E. Lantz.

Corresponding Secretary—N. Hollister

Treasurer—J W Gidley

Members of the Council—A D Hopkins, A. K. Fisher, Vernon Bailey, A. B. Baker and Paul Bartsch.

D. E LANTZ,
Secretary

A UNIVERSAL LAW[1]

Now that we appreciate fully that physics, geology, engineering, physiology, medicine, botany, zoology and biology are sub-divisions of the broader science of chemistry, we see that the chemist of the future must know a great deal more than any of us now do if he is to keep in touch with the whole subject Many people believe that this is impossible and that the scientific man of the future will be a narrow specialist, knowing only a small part of a single division of one science I do not believe this As we look back over the history of any science, we see always two opposing tendencies—one that complicates and one that simplifies The discovery of new facts makes a subject more complex and more difficult to grasp The discovery of new relations simplifies matters because it enables us to correlate facts and thus to get a better grasp of the subject[2]

In the chemistry of to-day we have three great, simplifying generalizations which are familiar to all of you · the atomic theory, the periodic law and the phase rule. These have long since proved their value as a means of correlating facts and as working hypotheses enabling us to predict new facts The value of these is not great, however, when we get beyond what is called chemistry in the narrower sense of the word

As one universal law we have the great, simplifying generalization known as the

[1] Address of the retiring president of the American Chemical Society at Minneapolis, December 28, 1910.

[2] Cf Bancroft, *Proc. Elisha Mitchell Soc.*, 20, 39, 1904

law of the conservation of energy. The marvelous effect of this in enabling one to correlate and remember apparently unrelated facts was brought out in a most striking way in Kundt's lectures on physics

I wish to call your attention to-night to what I believe to be another universal law, a qualitative one and not a quantitative one The chemists call it the theorem of Le Chatelier The physicists call it the theorem of De Maupertuis or the principle of least action By the biologists it is known as the law of the survival of the fittest, while the business man speaks of the law of supply and demand. The broadest definition of it is that a system tends to change so as to minimize an external disturbance

In chemistry proper and in physics we study chiefly the effects of temperature, pressure, concentrations, electricity and light, but in the natural-history sciences we must also take account of moisture, food and fertilizers, secretions, climate, etc

If we heat a liquid we convert a portion of the liquid into vapor, an operation which absorbs heat If we heat a saturated solution, the solubility increases if the solid dissolves with an absorption of heat. If we increase the pressure on a dissociating compound or if we increase the concentration of the dissociation products, we get a decrease of dissociation which involves a decrease in pressure and a decrease in the amount of the dissociation product If we pass an electric current through a solution, we tend to get a counter-electromotive force which cuts down the electrical stress If we have suspended particles in a liquid, a difference of potential causes them to move in the direction which reduces the electrical stress. Since all substances absorb light of some wave-length to a greater or less extent, all substances are light-sensitive to some rays and tend to change in such a way as to eliminate the strain caused by the light. Whether any measurable change takes place depends on other conditions With some silver salts or with Eder's solution of mercuric oxalate, we get visible decomposition With chromium salts we get no measurable change unless some reducing agent is present With some substances we get fluorescence or phosphorescence, but ordinarily without apparent change With a copper sulphate solution there is apparently no effect due to light Yet all these solutions are really light-sensitive and they all tend to change in the same way, namely, to eliminate the substance which absorbs the light

In the business world continuous over-production of any commodity necessitates a fall in the price of the article. Also, a sufficiently wide-spread and prolonged decrease in the demand for meat will bring down the price, at least temporarily This may not help the consumer, because he may have to pay more for fish, eggs and vegetables, but that is not our problem

If one should ship enough copper abroad as export copper and should bring it back as ballast, one would create a state of strain which would eventually play havoc with the price of copper It is said that this experiment was tried when the price of copper was over twenty cents, but the details have never been published Over-production of silver destroyed the ratio of sixteen to one, while over-production of gold is now said to be one of the factors in the high cost of living

In physiology and medicine we find many illustrations of our law. "When irritating substances get into the eye, a flow of tears occurs to wash them away; from the nose and respiratory passages, they are ejected by sneezing or by cough;

and from the stomach or intestines they are removed by the vomiting and purging to which they themselves give rise[3]

If a splinter lodges in one's finger and is not removed, festering occurs and the splinter is sloughed out The throwing off of a cold is merely the elimination by the system of the disturbing factors and the same may be said about the recovery from any disease. Herter[4] says that "disease is generally the expression of a reaction on the part of the cell to injurious influences"

When studying chemical reactions, we find some cases, such as the inversion of sugar, in which the reaction products have little or no effect on the reaction In many other cases, the reaction may come to an end if the reaction products are not removed In these latter cases the reaction products might be said to be toxic to the system Analogous cases occur in physiology Some secretions or reaction products are not toxic to the system, while others are Brunton[5] says that "cells excrete poisons formed within their bodies [and that] an excessive quantity of their own products is usually injurious to cells" We all know that the waste products of digestion must be removed from the intestines periodically or poisoning will ensue, and we also know that the system tends to react in such a way as to remove these products

In the cases thus far considered, it has been fairly clear what the response of the system would be, but this is not always so. If a man goes out into the street and slaps another man's face, he creates a state of strain, which may be relieved by the other man's running away It is quite possible, however, that the other man may knock the first man down, or he may hand the first man over to a policeman, if one happens to be near What happens depends on the relative sizes and temperaments of the two men and on the nearness of the policeman We can not make A, B and C represent the first man, the other man and the policeman, and then interchange the letters We have the same thing in mixtures of three liquids If we add one liquid to another, we always lower the vapor pressure of the second to a certain extent We can not make any such definite statement about what will happen if we add a third liquid to the other two The addition of the third liquid may decrease the partial pressures of both the other liquids or it may decrease the partial pressure of either one and increase that of the other We must know the specific properties of the liquids before we can predict what will happen

We know that an irritating substance is often removed from the stomach by vomiting, but if we administer poison continuously for a long time, the system tends to eliminate the irritating effect by becoming immune to the poison We need not hark back to the mythical case of Mithridates, who qualified for the throne by living on all the known poisons while young The case of the arsenic eaters is better authenticated[6] The whole of immuno-chemistry is an illustration of the applicability of our law[7]

The most interesting field for the study of our law is to be found in the natural history sciences. Here we must consider the survival of the race as well as the survival of the individual or we shall make

serious mistakes. Thus plants and trees often flower at an abnormal time after receiving serious injury.[8] This is really one form of tendency to eliminate the disturbing factor. One should also distinguish between the direct injury to the plant or animal and the change in the organism which enables it or its descendants to withstand the disturbing influences.

A great deal has been done in the way of collecting facts illustrating the effect of environment on plants and animals but the real reason for any particular change is rarely given,[9] and the change is only too often the resultant of two or more factors which are *not* differentiated carefully. I am going to cite some cases in which the application of the theorem of Le Chatelier is quite clear, and also others which seem interesting enough to warrant attention being called to them.

PRESSURE AND CONCENTRATION

The wind blows against the trees and the boughs bend so as to spill the wind. A prevailing wind from a given direction causes the trees to assume a permanent set. This is not especially interesting because this change is probably not inherited to any appreciable extent.

Bailey[10] has pointed out that plants tend to become circular instead of bilateral, because they are sessile.

They therefore found it to their advantage to reach out in every direction from their support in the search for food. Whilst the centrifugal arrangement has strongly tended to disappear in the animal creation, it has tended with equal strength to persist and to augment itself in the plant creation. Its marked development amongst plants began with the acquirement of terrestrial life, and with the consequent evolution of the asexual or sporophytic type of vegetation. Normally, the higher type of plant bears its parts more or less equally upon all sides, and the limit to growth is still determined by the immediate environment of the given individual or of its recent ancestors. Its evolution has been acephalic, diffuse or headless, and the individual plant or tree has no proper concentration of parts. For the most part it is filled with unspecialized plasma, which, when removed from the parent individual (as in cuttings or grafts), is able to reproduce another like individual. The arrangements of leaves, branches, the parts of the flower, and even of the seeds in the fruit, are thus rotate or circular, and in the highest type of plants the annual increments of growth are disposed in like fashion, and it is significant to observe that in the compositæ, which is considered to be the latest and highest type of plant-form, the rotate or centrifugal arrangement is most emphatically developed. The circular arrangement of parts is the typical one for higher plants, and any departure from this form is a specialization, and demands explanation.

In England rabbits are held in check, though with some difficulty. If the repressive factors are removed, as in Australia, the rabbits adapt themselves to the situation and multiply so as to become a veritable pest. In the same way the Russian thistle spread through the northwest some years ago. An insect will often adapt itself to changed conditions to such an extent as to take on new habits.[11]

An early naturalist traveling in Colorado found a striped beetle feeding upon wild solanums or nightshades. The insect came to be in demand among collectors, and it is said that handsome prices were paid for specimens for museums. In the course of time the settlers grew potatoes in Colorado and the insect took a fancy to them and spread rapidly. It is now known as the Colorado potato beetle. The first attacks were noticed about thirty years ago, but now the insect is a serious pest wherever potatoes are grown in quantity.

[10] "The Survival of the Unlike," 15, 1896.

[11] Cf. Bailey, "The Survival of the Unlike," 184, 1896.

The displacement of equilibrium due to cultivating large areas to one crop has led to an enormous increase in the number of insects and fungous enemies in any given region.[12]

The excessive ravages of insects in the United States are largely owing to the cultivation of their food plants in extended areas Two hundred years ago not even the wild crab, the earliest representative of the apple, existed in this country, and consequently there were no apple insects Later when a few apple trees became the adjunct of the simple homes of the early settlers, those of our insects to which they offered more desirable food than that on which they had previously subsisted were obliged to wing their way often for many miles in search of a tree on which to deposit their eggs. If birds were then abundant, how few of the insects could accomplish such extended flights! But in the apple orchards of the present day—some of them spreading in almost unbroken mass of foliage over hundreds of acres—our numerous apple insects may find the thrifty root, the vigorous trunk, the succulent twig, the tender bud, the juicy leaf, the fragrant blossom, and the crisp fruit spread out before them in broad array, as if it were a special offering to insect voracity, or a banquet purposely extending an irresistible invitation. . . . Careful cultivation has made it the best of its kind, appetite is stimulated, development is hastened, broods are increased in number, individuals are multiplied beyond the conservation of parasitic destruction, facilities of distribution are afforded with hardly a proper exercise of locomotive organs; and when these almost useless members have become absorbed, as in the wingless females of the bark-louse and the canker worms, the interlocking branches afford convenient passage from tree to tree

As Bailey[13] says:

We, as horticulturists, are every year planting new invitations to insect and fungous attacks. If we take this extra risk, we must certainly prepare ourselves to meet it Our fathers' weapons can not avail against the hords of invaders which we are inviting to our doors. They are coming up out of the woods and the swamps and the bare fields to regale themselves at the banquet which we have spread.

Cultivation affords places of less struggle than organisms are forced to occupy under normal conditions. Man disturbs the equilibrium or removes the pressure in some direction, and a multitude is waiting to spring into the void The great potato fields not only provided food, but there were few other insects to dispute the possession of them, the Colorado solanum beetle saw his opportunity, and improved it He has been a successful bug This release of the natural tension, which cultivation affords, is to my mind the most potent factor in the increase of our little foes

TEMPERATURE

One effect of a lower temperature is obviously to produce a better protective coating on animals, while a higher temperature acts in the opposite way I quote a few special cases from Darwin [14]

According to Roulin, the semi-feral pigs in the hot valleys of New Granada are very scantily clothed, whereas, on the Paramos, at the height of 7,000 to 8,000 feet, they acquire a thick covering of wool lying under the bristles, like that on the truly wild pigs of France

Roulin asserts that the hides of the feral cattle on the hot Llanos are always much less heavy than those of the cattle raised on the high platform of Bogota, and that these hides yield in weight and in thickness of hair to those of the cattle which have run wild on the lofty Paramos The same difference has been observed in the hides of cattle reared on the bleak Falkland Islands and on the temperate Pampas

Great heat seems to act directly on the fleece several accounts have been published of the change which sheep imported from Europe undergo in the West Indies. Dr Nicholoson, of Antigua, informs me that, after the third generation, the wool disappears from the whole body, except over the loins, and the animal then appears like a goat with a dirty door mat on its back A similar change is said to take place on the west coast of Africa. On the other hand, many wool-bearing sheep live on the hot plains of India. Roulin asserts that in the lower and heated valleys of the Cordillera, if the lambs are sheared as soon as the wool has grown to a certain thickness, all goes

[12] Lintner, First Report State Entom. N. Y, 10, 1882.

[13] "The Survival of the Unlike," 187, 1896.

[14] "Animals and Plants under Domestication," 2d ed., 1, 81, 95, 102, 1890.

on afterwards as usual; but if not sheared, the wool detaches in flakes, and short shining hair like that of a goat is produced afterwards This curious result seems merely to be an exaggerated tendency natural to the Merino breed, for as a great authority, namely, Lord Somerville, remarks, "the wool of our Merino sheep after shear time is hard and coarse to such a degree as to render it almost impossible to suppose that the same animal could bear wool so opposite in quality, compared to that which has been clipped from it, as the cold weather advances, the fleeces recover their soft quality" As in sheep of all breeds the fleece naturally consists of longer and coarser hair, covering shorter and softer wool, the change which it often undergoes in hot climates is probably merely a case of unequal development; for even with those sheep which like goats are covered with hair, a small quantity of underlying wool may always be found In the wild mountain sheep (*Ovis montana*) of North America there is an analogous change of coat;[15] the wool begins to drop out in early spring, leaving in its place a coat of pelage quite different in character from the ordinary thickening—for instance, in the horse, the cow, etc, which shed their winter coat in the spring.

The fact of there being wool-bearing sheep in the hot plains of India is not necessarily a contradiction of the general law, because the tendency to change may be counteracted by careful selection [16]

M Lasterye, after discussing this subject, sums up as follows: "The preservation of the Merino race in its utmost purity at the Cape of Good Hope, in the marshes of Holland, and under the rigorous climate of Sweden, furnishes an additional support of this my principle, that fine-wooled sheep may be kept wherever industrious men and intelligent breeders exist.

If we remove a plant to a climate where frosts occur earlier, the chances are very good that the plant will be killed before the seeds ripen. If the variety is to survive, an early-ripening form must develop This actually happens with wheat.[17]

[15] Audubon and Bachman, "The Quadrupeds of North America," 5, 365, 1846.

[16] Darwin, "Animals and Plants under Domestication," 2d ed., 1, 103, 1890.

[17] Darwin, "Animals and Plants under Domestication," 2d ed., 1, 333, 1890.

Wheat quickly assumes new habits of life. The summer and winter kinds were classed by Linnæus as distinct species; but M Monnier has proved that the difference between them is only temporary. He sowed winter wheat in the spring, and out of one hundred plants four alone produced ripe seeds; these were sown and resown, and in three years plants were reared which ripened all their seed. Conversely, nearly all plants raised from summer wheat, which was sown in autumn, perished from frost; but a few were saved and produced seed, and in three years this summer variety was converted into a winter variety Hence it is not surprising that wheat soon becomes to a certain extent acclimatised, and that seed brought from distant countries and sown in Europe, vegetates at first or even for a considerable period, differently from our European varieties In Canada the first settlers, according to Kalm, found their winters too severe for winter wheat brought from France, and their summers often too short for summer wheat, and they thought that their country was useless for corn crops until they procured summer wheat from the northern part of Europe, which succeeded well

Another interesting case is that of corn, also cited by Darwin.[18]

The tall kinds grown in southern latitudes, and therefore exposed to great heat, require from six to seven months to ripen their seed; whereas the dwarf kinds, grown in northern and colder climates, require only from three to four months. Peter Kalm, who particularly attended to this plant, says, that in the United States in proceeding from south to north, the plants steadily diminish in bulk. Seeds brought from lat. 37° in Virginia, and sown in lat. 43°–44° in New England, produce plants which will not ripen their seed, or ripen them with utmost difficulty. So it is with seed carried from New England to lat. 45°–47° in Canada. By taking great care at first, the southern kinds after some years' culture ripened their seed perfectly in their northern homes, so that this is an analogous case with that of the conversion of summer into winter wheat, and conversely. When tall and dwarf maize are planted together, the dwarf kinds are in full flower before the others have produced a single flower, and in Pennsylvania they ripen their seeds six weeks earlier than the tall maize. Metzger also mentions a European maize which

[18] "Animals and Plants under Domestication," 2d ed., 1, 341, 1890.

ripens its seed four weeks earlier than another European kind. With these facts so plainly showing inherited acclimatisation, we may readily believe Kalm, who states that in North America maize and some other plants have gradually been cultivated further and further northward.

The peach tree offers another good instance of acclimatization.[19]

Mr Crozier records testimony to the effect that peach trees in Michigan were injured no more at a temperature of twenty degrees below zero than they were in central Mississippi at a temperature of zero. Peach buds are injured at a much higher temperature at the south than at the north. Mr P. H. Mell, Jr., director of the Alabama Polytechnic Institute at Auburn, writes me that buds are often killed even at a temperature of 34 to 38 degrees above zero. This observation undoubtedly refers to the partially expanded buds, yet it is well known that at the north a considerable frost is required to kill the swelling buds. It is possible that all these instances of the peach should fall under the division of adaptation through modification of individual constitution, but as I can not be certain, if indeed it is probable, that all these cases represent bud offspring, I place the statement here. If trees of the same variety show this difference in different latitudes, as they undoubtedly often do, then we have indisputable evidence of the acclimatizing of the individual.

Bailey's quotation from Cooper as to watermelons also has a bearing on this matter.[20]

A striking instance of plants being naturalized happened by Colonel Matlack sending some watermelon seed from Georgia, which, he informed me [Cooper] by letter, were of superior quality. Knowing that seed from vegetables which had grown in more southern climates required a longer summer than what grew here, I gave them the most favorable situation, and used glasses to bring them forward, yet very few ripened to perfection, but finding them to be so excellent in quality as described, I saved seed from those first ripe; and by continuing that practise four or five years, they became as early watermelons as I ever had.

Changes in the colors of some butterflies can be obtained by varying the temperature during the pupal stage of development. While we are not able to prove that these changes are beneficial adaptations, it is interesting to note that these changes characterize the same butterflies in arctic and tropic regions.[21]

Warmth acting on pupæ of *V. Cardui* (painted lady), gave an extraordinarily pale form, like those found in very different parts of the tropics. Cold, on the other hand, gave specimens with a very recognizable darkening of the whole insect, such as is exhibited by a form found in Lapland.

We have no clue[22] at all as to the influence a low temperature has upon the production of wings in aphides. "As long as the temperature is high and the moisture sufficient, plant lice are wingless, but if the temperature be lowered, wings begin to grow." The problem is an interesting one and should not be difficult to solve with the aid of the theorem of Le Chatelier.

LIGHT

Since light tends to destroy any substance which absorbs it, it seems at first sight as though transparent, colorless plants and animals would be the surviving type in the intense light of the tropics. Light does tend to bleach organic colors, but the flaw in the reasoning is that we are dealing with living organisms.[23] It is easier for a man or an animal to develop a pigmented coating and thus eliminate the chemical action of light on blood[24] than for it to acquire the habit of living without red corpuscles. It is evidently better for a plant to develop chlorophyll and a healthy

[19] Bailey, "The Survival of the Unlike," 325, 1896.

appetite for carbon dioxide than for it to be bleached by the light.

Consequently we find that man is invariably covered with a pigment which acts as an armor to exclude the more harmful short rays, and moreover the amount of pigment is in direct proportion to the intensity of the light of the country to which his ancestors have proved their adjustment by centuries or millenniums of survival in health and vigor. It is a simple matter of mathematics to show that the intensity of light under the zenith sun in the tropics is the greatest, and that the amount of rays per unit of surface diminishes as we go north in proportion to a function of the latitude. In addition to this, the further from the tropics we go the greater is the layer of air which the rays must pass through and the more of them which are absorbed. Hence we can reach a latitude where there is insufficient light for plant growth even if there could be sufficient warmth. Yet man flourishes in these regions, and so do other animals. Hence we find the greatest pigment in the tropics among the Australians, New Guineas, Negritos, East Indians and African Negroes, some of whom are nearly jet black. As we go north from the tropics we find the complexions gradually lightening, being dark brown in Egypt, light brown in north Africa states, deep olive in the Mediterranean, olive in southern Europe, brunette in central Europe and blond in the northwestern sections of Europe, embraced by a curve passing through northern France, northern Germany and northwest Russia.

Undoubtedly the negro, while in the shade, is able to radiate heat better than whites, and this enables him to keep cool in the tropics, but puts him at a disadvantage in the north where the white man can keep warmer with less clothing and less fire in the house. But it is a secondary cause enhancing the first, because when it comes to a question of light and cold, nature makes no mistakes, but selects a color able to exclude the light. Hence in all cold light countries, *i. e.*, steppes, plains, and the arctics, there is a pigmentation of a color in the lower end of the spectrum, red or yellow, with variations of brown, olive or copper. As a rule the color is markedly light yellow in cold, light countries, as in North China.

In America we had every shade from the blackest Indians of tropical South America through all the shades of copper and brown to the very light, almost white Indians of the northeastern part of the United States, who had conditions very similar to those suited for the blonds of Europe. In Italy, Spain and China, we find the same thing, for the men of the south are markedly darker than those of the north.

The same law holds in France, Germany, Russia, Persia and India: the north is decidedly blonder than the south, and the same is found in the British Islands, but in a much modified way. Even the Ainos in the north of Japan are said to be lighter than the Japanese.

All these red and yellow colors undoubtedly enable the native to conserve his heat almost as well as the white man, and at the same time exclude the dangerous short waves.

In Africa, Eimer[25] found that in passing up the Nile valley from the Delta to the Soudan, the natives gradually became more and more dark-skinned the further south they lived.

Woodruff[26] recommends that white men in the tropics should wear white outer garments and black underclothes, which constitutes a pretty fair imitation of a dark-skinned Arab in a white burnous.

Vernon[27] points out "that the diminution or disappearance of pigmentation following upon withdrawal of light, is best illustrated by reference to the well-known cave animals. Of these, one of the most interesting is *Proteus anguineus*, which is found in the subterranean caves of the Karst Mountains about Adelsberg. This amphibian is almost white, but if kept for some time in the light, it gradually becomes pigmented. Pigment cells are, in fact, still present in its skin, and in all probability these are directly stimulated to exert their function by the action of the light." If Vernon had been familiar with the theorem of Le Chatelier, he would have worded this last sentence very differently.

In the case of heliotropism, the animals

[25] "Organic Evolution," 88, 1890.

[26] "Effects of Tropical Light on White Men," 321, 1905.

[27] "Variation in Animals and Plants," 250, 1903.

turn automatically to or from the source of light, depending on whether they are positively or negatively heliotropic In some cases they also move automatically towards or away from the light Loeb[28] says in regard to this·

This automatic orientation is determined by two factors, first a peculiar photo-sensitiveness of the retina (or skin), and second a peculiar nervous connection between the retina and the muscular apparatus In symmetrically built heliotropic animals in which the symmetrical muscles participate equally in locomotion, the symmetrical muscles work with equal energy as long as the photo-chemical processes in both eyes are identical If, however, one eye is struck by stronger light than the o her, the symmetrical muscles will work unequally and in positively heliotropic animals those muscles will work with greater energy which bring the plane of symmetry back into the direction of the rays of light and the head towards the source As soon as both eyes are struck by the rays of light at the same angle, there is no more reason for the animal to deviate from this direction and it will move in a straight line All this holds good on the supposition that the animals are exposed to only one source of light and are very sensitive to light.

Loeb[29] has also shown that the heliotropism may sometimes be modified or even reversed by adding certain chemicals to the water He has also shown[30] that some animals seek automatically the places where the intensity of light is a minimum, but that this is not negative heliotropism because the animals do not necessarily move along the path of the ray In all these cases we have an application of our law, because the animals arrange themselves so as to minimize the state of stress

It had always seemed to me a most mysterious thing that animals should be heliotropic, until it finally dawned on me that we are all of us heliotropic to a certain extent. Place a man out in an intense light and, if he can not shade his eyes, it will take a pretty strong special stimulus to keep him from turning his back to the light If his eyes happen to be weak, he will respond more promptly and more automatically to the light He is negatively heliotropic to strong light. I am inclined to think that man is positively heliotropic to a faint light, because he would certainly tend to turn towards the point that he could see We can also find an analogy to the case of the animals which congregated at the places where the intensity of light is a minimum Place a man out on the desert in blazing sunlight and it will take a strong counter-stimulus to keep him from moving into any shade that he can find Here the irritation is due to heat and not to light; but the man is not negatively thermotropic because he will move across the temperature gradient in order to reach the shade

Of course the reflex action is not relatively so powerful with man as with the lower animals. In fact, Loeb[31] says that "it rarely happens that animals endowed with the mechanisms of associated memory react in such a machine-like manner to the elementary forces of nature as the heliotropic animals which we have discussed"

Vernon[32] points out that

If plants be allowed to grow in absolute darkness, they, as a rule, become very much elongated in form whilst their leaves are small and ill shaped . Sachs found that potato tubers grown in darkness for fifty-three days produced sprouts from 150 to 200 mm high, whilst similar ones grown in daylight were only 10 to 13 mm. high Again he found that the hypocotyl of the buckwheat (*Fagopyrum*) reached a height of 35 to 40 cm. in the dark, whilst it grew only to 2 or 3 cm when freely exposed to light. K. Goebel

[28] "Darwin and Modern Science," 264, 1909

[29] "The Dynamics of Living Matter," 131, 1906, "Darwin and Modern Science," 265, 1909.

[30] Loeb, "The Dynamics of Living Matter," 136, 1906.

[31] "The Dynamics of Living Matter," 135, 1906

[32] "Variation in Animals and Plants," 245, 1903.

has shown that if cactuses are cultivated in darkness, their form changes completely. The young shoots are rounded, and fail to show the angular irregularities of form which increase the surface capable of effecting assimilation under the influence of light

Since the leaves especially are effective in the light, the absence of light will prevent normal development of the leaves and this seems to be the chief direct effect If the plant does not have to develop leaves to any extent, there is more food available for the stem; and the growth of the stem is thus really a secondary effect The matter is still further complicated by the fact that the moisture content and the carbon dioxide content of the air were not kept constant during the two sets of experiments

An increase in the intensity of the light is often accompanied by a decrease in the surface of the leaf and an increase in the thickness [33] I think that it is a mistake to attribute this change to the action of light alone It is more the combined effect of light and dryness, or of light and the higher rate of evaporation due to a higher temperature With decreased surface and greater thickness there is less evaporation, one extreme of which is reached in the eucalyptus with its leaves turned edgewise. The assimilation of food is provided for by an increased thickness of the chlorophyll layer, because the more intense light can penetrate farther into the leaf

We have seen that the pigment in the negro's skin is essentially protective in action A thicker or coarser leaf may also be a protection against too intense a light Rowlee[34] found that "intense light does not kill thick, coriaceous or succulent leaves with heavy cutinized external walls . . . doubtless owing to the screening effect of the heavy walls or cells containing much water."

We have not sufficient data to make it possible to say why an increase in the intensity of light causes the change from sexual to asexual reproduction in some algæ and the reverse change in others,[35] but we can be quite certain that both changes are in conformity with the theorem of Le Chatelier.

MOISTURE

Vernon[36] says that "the effect of a dry soil and atmosphere is well shown by the characters of desert plants These are stunted in growth, and are of a nearly uniform gray color, owing to their intense hairiness. The leaves are more fleshy, and there is a great tendency to the formation of spines. That these characters are in part at least the direct result of want of water is shown by the fact that they may disappear if water is supplied." The development of hairs is of great advantage to a plant in an arid climate, especially if there is any wind The circulation of air, and consequently the rate of evaporation is impeded by the mass of hairs

We get characteristic changes when plants, normally terrestrial, are grown in water.[37]

As regards the leaves, it is well known that when aerial and floating leaves are present on the same aquatic plant, they differ greatly in structure, and as a rule also in form, from the submerged leaves. In *Ranunculus heterophyllus* and *Cabomba aquatica*, for instance, the floating leaves are more or less rounded, whilst the submerged ones have dissected and filiform segments In *Hippuris* (mare's tail) the aerial and floating leaves are short, and in *Callitriche* rounded, but

[33] Vernon, "Variation in Animals and Plants," 248, 1903.

[34] Proc. 19th Meeting Soc Promotion Agric. Science, Boston, 1898.

[35] Loeb, "Darwin and Modern Science," 230, 1909.

[36] "Variation in Animals and Plants," 263, 1903.

[37] Cf. Vernon, "Variation in Animals and Plants," 266, 1903

the submerged leaves of both are linear or ribbon-like. In all cases the submerged leaves are of a more delicate texture, more or less translucent, and of a brighter green color than the others.

This is a much more complex case than Vernon realizes. Submerged leaves do not develop the supporting frame of the aerial leaves. The delicate texture is therefore to a great extent a result of the supporting power of the water and not of its wetness. Since the supporting structure of the aerial leaf is not developed when the leaf is submerged, the leaf grows longer, just as the stem of the plant grows longer in the dark because the leaves develop but slightly. The thinness of the leaf is probably chiefly a result of the decreased intensity of light. This is the best analysis that can be given at present, but it brings out clearly how slack people have been in controlling conditions.

The effect of excessive moisture or aridity upon plants is similar in type[38] to the effect of heat or cold on the pupæ of butterflies.

The relation of leaf form to environment has often been investigated and is well known. The leaves of bogs and water-plants afford the most striking examples of modifications: according as they are grown in water, moist or dry air, the form of the species characteristic of the particular habitat is produced, since the stems are also modified. To the same group of phenomena belongs the modification of the forms of leaves and stems in plants or transplantation from the plains to the mountains or *vice versa*. Such variations are by no means isolated examples. All plants exhibit a definite alteration in form as the result of prolonged cultivation in moist or dry air, in strong or feeble light or in darkness, or in salt solutions of different composition and strength.

The last sentence in the preceding paragraph is interesting for what it does not say. There is no indication that Klebs has any inkling of the universal law underlying all these changes.

[38] Klebs, "Darwin and Modern Science," 235, 1909.

FOOD AND FERTILIZERS

It seems evident that an exuberant growth would be favorable to variability and to the development of sports. This is universally recognized to be the case. Thus Darwin[39] says:

Of all the causes which induce variability, excess of food, whether or not changed in nature, is probably the most powerful. This view was held with regard to plants by Andrew Knight and is now held by Schleiden, more especially in reference to the inorganic elements of the food. In order to give a plant more food, it suffices in most cases to grow it separately, and thus prevent other plants robbing its roots. It is surprising, as I have often seen, how vigorously our common wild species flourish when planted by themselves, though not in highly manured land; separate growth is, in fact, the first step in cultivation, we see the converse of the belief that excess of food induces variability in the following statement by a great raiser of seeds of all kinds: "It is a rule invariably with us, when we desire to keep a true stock of any one kind of seed, to grow it on poor land without dung, but when we grow for quantity we act contrary, and sometimes have dearly to repent of it." According also to Carrière, who had great experience with flower-garden seeds, "On remarque en général les plantes de vigeur moyenne sont celles qui conservent le mieux leurs caractères."

Under the heading of effect of cultivation, Klebs[40] says:

It is however a fact that if a plant is removed from natural conditions into cultivation, a well-marked variation occurs. The well-known plant breeder, L. de Vilmorin, speaking from his own experience, states that a plant is induced to *affoler*, that is, to exhibit all possible variations from which the breeder may make a further selection only after cultivation for several generations. The effect of cultivation was particularly striking in *Veronica chamaedrys*, which, in spite of its wide distribution in nature, varies very little. After a few years of cultivation this "good" and constant species becomes highly variable. The specimens on which the experiments were made were three modified inflorescence cuttings, the

[39] "Animals and Plants under Domestication," 2d ed., 2, 214, 1890.

[40] "Darwin and Modern Science," 245, 1909.

parent plants of which certainly exhibited no striking abnormalities In a short time many hitherto latent potentialities became apparent, so that characters, never previously observed, or at least very rarely, were exhibited, such as scattered leaf arrangements, torsion, terminal or branched inflorescences, the conversion of the inflorescence into foliage shoots, every conceivable alteration in the color of flowers, the proliferation of flowers.

One more quotation will suffice, this time from Bailey [41]

Now let us endeavor to put ourselves in nature's place, if such a conception is possible, and to briefly follow an outline of her methods with plants. We shall find that variation is largely the result, so far as we can see, of excess of food supply. The seedsman knows that heavy lands make his seed crops break into non typical forms, and he therefore prefers, for most plants, a soil not very rich in nitrogen or growth production Heavy soils make the dwarf peas "viney," and bud sprouts of curious leaves and flowers are wont to appear upon over vigorous shoots

Since conditions which tend to shorten the life of a plant or tree often cause the plant or tree to flower,[42] it follows that conditions which favor a rank growth are likely to be disadvantageous to the production of flowers This is actually the case [43]

One extreme case, that of exceptionally early flowering, has been observed in nature and more often in cultivation. A number of plants under certain conditions are able to flower soon after germination. This shortening of the period of development is exhibited in the most striking form in trees, as in the oak,[44] flowering seedlings of which have been observed from one to three years old, whereas normally the tree does not flower until it is sixty or eighty years old

Another extreme case is represented by prolonged vegetative growth leading to the complete suppression of flower-production. The result may be obtained with several plants, such as *Glechoma*, the sugar beet, *Digitalis*, and others, if they are kept during the winter in a warm, damp atmosphere, and in rich soil, in the following spring or summer they fail to flower Theoretically, however, experiments are of greater importance in which the production of flowers is inhibited by very favorable conditions of nutrition occurring at the normal flowering period Even in the case of plants of *Sempervivum* several years old, which, as is shown by control experiments on precisely similar plants, are on the point of flowering, flowering is rendered impossible if they are forced to very vigorous growth by an abundant supply of water and salts in the springs Flowering, however, occurs, if such plants are cultivated in relatively dry soil and in the presence of strong light. Careful researches into the conditions of growth have led, in the case of *Sempervivum*, to the following results (1) With a strong light and vigorous carbon assimilation in strong light, a considerably increased supply of water and nutritive salts produces active vegetative growth (2) With vigorous carbon assimilation in strong light, and a decrease in the supply of water and salts, active flower production is induced. (3) If an average supply of water and salts is given, both processes are possible; the intensity of carbon assimilation determines which of the two is manifested A diminution in the production of organic substances particularly of carbohydrates, induces vegetative growth This can be effected by culture in feeble light or in light deprived of the yellow-red ray on the other hand, flower-production follows increase in light intensity These results are essentially in agreement with well known observations on cultivated plants, according to which, the application of much moisture, after a plentiful supply of manure composed of inorganic salts, hinders the flower production of many vegetables, while a decrease in the supply of water and salts favors flowering

Good manuring is in the highest degree favorable to vegetative growth, but is in no way equally favorable to the formation of flowers The constantly repeated expression, good or favorable nourishment, is not only vague but misleading, because circumstances favorable to growth differ from those which promote reproduction; for the production of every form there are certain favorable conditions of nourishment, which may be defined for each species. Experience shows

[41] "The Survival of the Unlike," 169, 1898

[42] Möbius, "Beiträge zur Lehre von der Fortpflanzung der Gewächse," 7, 125, 1897

[43] Klebs, "Darwin and Modern Science," 232, 246, 1909

[44] Möbius, "Beiträge zur Lehre von der Fortpflanzung der Gewächse," 89, 1897 [The conditions are not given by Möbius —W. D B]

that, within definite and often very wide limits, it does not depend on the *absolute amount* of the various food substances, but upon their respective degrees of concentration As we have already stated, the production of flowers follows a relative increase in the amount of carbohydrates formed in the presence of light, as compared with the inorganic salts on which the formation of albuminous substances depends[44] The various modifications of flowers are due to the fact that a relatively too strong solution of salts is supplied to the rudiments of these organs. As a general rule every plant form depends upon a certain relation between different chemical substances in the cells and is modified by an alteration of that relation

Vernon[45] cites some interesting cases in which changes of diet have apparently produced results in accordance with our law

John Hunter observed a most marked thickening and hardening in the stomach of a gull (*Larus tridactylus*) which had been fed for a year on grain It is stated by Dr Edmonston that a similar change takes place under natural conditions every year in the stomach of the common herring gull (*Larus argentatus*) Thus in the Shetland Islands this bird feeds in the winter on fish, but in the summer frequents the cornfields and feeds on grain Dr Edmondston has also noticed a somewhat similar change in the stomach of a raven which had been fed for a long time on vegetable food Again, Menetries found that in an owl (*Strix Gallaria*) the effect of vegetable diet was to change the form of the stomach and make the inner coat leathery.

The converse experiment of feeding graminivorous birds on a flesh diet has been made by Dr Holmgren By feeding pigeons on meat for a considerable time, he found that the gizzard gradually acquired the qualities of a carnivorous stomach Again Delage fed a fowl for three years on meat, and found that the muscular substance of its gizzard was considerably decreased. All these results, though apparently so unequivocal, have not passed unchallenged; for G. Brandes,[47] who fed both flesh-feeding birds on grain, and grain feeders on flesh, states that he was unable to trace any adaptation to the altered conditions in either case.

Since these alleged changes are directly in line with the cases previously quoted, of the changes in butterflies and bog plants, it seems probable that the negative results are due to error. It is very desirable, however, that this point should be settled definitely one way or the other.

A very complicated case of the effect of the environment, and one which I shall *not* attempt to account for, is cited by Poulton[48]

Entirely new light upon the seasonal appearance of epigamic characters is shed by the recent researches of C W. Beebe,[49] who caused the scarlet tanager (*Piranga erythromelas*) and the bobolink (*Dolichonyx oryzivorus*) to retain their breeding plumage through the whole year by means of fattening food, dim illumination and reduced activity Gradual restoration to the light and the addition of meal-worms to the diet invariably brought back the spring song, even in the middle of winter A sudden alteration of temperature, either higher or lower, caused the birds nearly to stop feeding, and one tanager lost weight rapidly and in two weeks moulted into the olive-green winter plumage. After a year, and at the beginning of the normal breeding season, "individual tanagers and bobolinks were gradually brought under normal conditions and activities"; and in every case moulted from nuptial plumage to nuptial plumage "The dull colors of the winter season had been skipped" The author justly claims to have established "that the sequence of plumage in these birds is not in any way predestined through inheritance . .," but it may be interrupted by certain factors in the environmental complex.

SECRETIONS

Under physiology and medicine mention has previously been made that many organisms give rise to products which are toxic to the organism and which must be removed. Brunton[50] points out that "an excessive quantity of their own products is usually injurious to cells and too much alcohol will stop the growth of yeast At

[44] Klebs, "Künstliche Metamorphosen," 117.

[45] "Variation in Animals and Plants," 295, 1903.

[47] Biol. Centralblatt, 16, 825.

[48] "Darwin and Modern Science," 297, 1909.

[49] *The American Naturalist*, 42, 34, 1908.

[50] "Darwin and Modern Science," 174, 1909.

the same time these products are frequently very nutritious for cells of a different sort and alcohol furnishes a most suitable pabulum for the organisms which produce vinegar. Vinegar in its turn is toxic to the microbe which produces it, but serves again as a soil for another which gives rise to a viscous fermentation. By the successive action of these ferments a solution of sugar may produce, first, alcohol, secondly, vinegar, and thirdly, ropy mucus. In this particular series each microbe produces a substance injurious to itself but useful to its successor. This is, however, not always the case because a cell may produce a substance not only injurious to itself but injurious to other cells, and alcohol in large quantity not only kills the cells of yeasts, but other cells as well. Similar conditions occur within living organisms where the cells composing the different parts are connected together and pass on the products of their life from one cell to another by means of the circulation of the blood and tissue juices. The secretions of one part may be, and indeed generally are, useful to other parts of the organism and so long as no part sins, either by deficiency or excessive action, the whole organism maintains a condition of health. But this is not always the case and health may be destroyed by (*a*) excessive, (*b*) defective or (*c*) prevented action of one or more of the parts composing the body."

Vernon[51] has tested the influence of the excreta of adult echinoids upon larval growth.

Echinoids of known weight were kept for a known time in a known volume of water, so that, on determining the absolute effect produced on larvæ grown in this water it was possible to calculate the relative effect produced by unit weight of echinoids kept for unit time in unit volume of water. On growing larvæ in water previously fouled by adult echinoids of their own species, it was found that, as a mean of five observations, they were diminished in relative size by 2.6 per cent., whilst only 41 per cent. of the ova employed reached the larval stage. On growing them in water fouled by echinoids of other than their own species, the larvæ, as a mean of five observations, were diminished by only 1.9 per cent., whilst 54 per cent of the ova reached the larval stage. That is to say, the products of excretion of an echinoid act more adversely both on the death rate and on the growth of embryos if these belong to its own species than if they belonged to another species. At least this is the case with *Strongylocentrotus*, *Sphærechinus* and *Echinus*. With two other (physiologically) less closely related species, viz., *Arbacia pustulosa* and *Dorocidaris papillata*, it was even found that the products of excretion, so far from acting adversely on growth, actually favored it. Thus *Strongylocentrotus* larvæ grown in water fouled by these two species were increased in size by respectively 4.3 and 1.7 per cent., whilst respectively 81 and 50 per cent. of the ova employed reached the pluteus stage.

Vernon[52] points out also that "De-Varigny actually found that snails grown in water in which other snails had already been growing several months were distinctly smaller than those grown in fresh water, and if the excreta of snails had been added as well they were smaller still."

The experiments of Warren[53] show that water fouled by *Daphnia* becomes specifically injurious to *Daphnia*, "for when the *Daphnia* are fast disappearing, there may be a swarm of ostracods or copepods (still living healthily in the water)."

If we were to reason from these facts to the behavior of crops, such as wheat, for instance, we should conclude that wheat unquestionably secretes substances which are toxic to itself and that the development of that crop or of a subsequent one

[51] "Variation in Animals and Plants," 298, 1903.

[52] "Variation in Animals and Plants," 305, 1903.

[53] Vernon, "Variation in Animals and Plants," 309, 1903.

would depend in part on the degree of the accumulation of the toxic substances in the soil. If the toxic substances were removed or destroyed sufficiently rapidly, no deleterious result would occur, but, otherwise, there would be one We should also conclude that the secretions from the wheat would not necessarily be toxic to other crops These *a priori* predictions seem to be confirmed by the facts

Cameron[34] points out that

It has been found that as a general rule the continued growth of one crop in any soil results in a low crop production Pot cultures have given even more pronounced results in the same direction The explanation long accepted is that the soil has, as a result of the continued cropping, become deficient in one or more of the "available" mineral nutrients Pot experiments, where the garnered crop was returned to the soil and still diminished yield was obtained, throw doubt on this explanation. Still further doubt results from water cultures which, by growing a crop in them, become "poor" for subsequent crops, although there is maintained in them an ample supply of mineral plant nutrients, and they are easily renovated by good adsorbers. These facts find a more satisfactory explanation as being due to the production in the nutrient medium of deleterious organic substances originating in the growing plant itself. This idea seems to have been advanced first by De Candolle, in 1832, to account for the beneficial results obtained by employing a rotation of crops It appears to have been held by Liebig at one time, although he subsequently abandoned it in favor of the view that the benefits of a crop rotation are due to the several crops requiring different proportions of mineral nutrients, and that the disturbance of the balance in the soil produced by one crop is not unfavorable to the growth of some other crop. Although lacking direct experimental confirmation, this latter view of Liebig's has long prevailed among agricultural investigators, partly by reason of his authority, partly by reason of the dominance of the plant food theory of fertilizers, and partly by reason of the fact that the ideas of De Candolle, as originally advanced, include certain errors soon detected The trend of recent investigations has been distinctly in favor of a modified form of the view of De Candolle It has been recognized that other factors enter into crop rotations, such as the elimination of associated weeds, various kinds of animal, insect and plant parasites, preparation of the soil by a deep-rooted crop for a shallow-rooted following crop, etc It has come to be recognized that there are natural associations of plants and natural rotations of vegetation certainly determined by other than plant food factors Thus, in the eastern United States, wheat is followed by ragweed naturally, while, across the fence cocklebur and wild sunflowers come in after the corn, the difference in vegetation being as sharply marked after the removal of the crops as when they still occupied the land Analyses of the ragweed, for instance, although it is a shallower rooted crop than wheat, show that it takes from the soil as much of the mineral nutrients as does the preceding wheat crop The investigation of Lawes and Gilbert on fairy rings showed that the continual widening of the rings can not be satisfactorily explained by the comparison of the mineral constituents in the soil within and without the rings. Work at Woburn on the effect of grass on apple trees finds no other plausible explanation than that the growing grass produces in the soil organic substances detrimental to young apple trees A number of similar cases have been recorded

[34] *Jour. Phys. Chem.*, 14, 425, 1910

CLIMATE

When seeds are planted in a new locality, a great many conditions are varied simultaneously and it is difficult, usually impossible, to tell to what extent each factor causes the changes that actually take place or why any given change is beneficial If we compare two varieties of the same plant, it seems reasonable to suppose, unless proof to the contrary is given, that the local variety is fairly well adapted to the local conditions, in which case one would expect the foreign variety to vary towards the local one Darwin[35] cites a case of this sort.

The effects of climate of Europe on the American varieties [of maize] is highly remarkable Metzger obtained seed from various parts of

[35] "Animals and Plants under Domestication," 2d ed., 1, 340, 1890.

America, and cultivated several kinds in Germany I will give an abstract of the changes observed in one case, namely, with a tall kind (*Breit-kornger Mais, Zea altissima*) brought from the warmer parts of America During the first year the plants were twelve feet high, and a few seeds were perfected, the lower seeds in the ear kept true to their proper form, but the upper seeds became slightly changed. In the second generation the plants were from nine to ten feet in height, and ripened their seed better, the depression on the outer side of the seed had almost disappeared, and the original beautiful white color had become duskier Some of the seeds had even become yellow, and in their now rounded form they approached common European maize. In the third generation nearly all resemblance to the original and very distinct American parent-form was lost In the sixth generation this maize perfectly resembled a European variety, described as the second sub-variety of the fifth race When Metzger published his book, this variety was still cultivated near Heidelberg, and could be distinguished from the common kind only by a somewhat more vigorous growth

Bailey[56] draws the following conclusion in regard to American fruits and American climate

American fruits constantly tend to diverge from the foreign types which were their parents, and they are, as a rule, better adapted to our environments than foreign varieties are In less than a century we have departed widely from the imported varieties which gave us a start At the expiration of another century we should stand upon a basis which is nearly if not wholly American

Darwin[57] notes a similar case.

Mr Meehan has compared twenty nine kinds of American trees with their nearest European allies, all grown in close proximity and under as near as possible the same conditions. In the American species he finds, with the rarest exceptions, that the leaves fall earlier in the season and assume before their fall a brighter tint; that they are less deeply toothed or serrated; that the buds are smaller, that the trees are more diffuse in growth and have fewer branchlets, and lastly, that the seeds are smaller—all in comparison with the corresponding European species. Now considering that these corresponding trees belong to different orders, and that they are adapted to widely different stations, *it can hardly be supposed that their differences are of any special service to them in the new and old worlds,*[58] and, if so, such differences can not have been gained through natural selection, and must be attributed to the long continued action of a different climate

As a matter of fact, most of these changes are just what would be beneficial in a country having a hot, dry, summer with a relatively long winter If planted in a very moist place, the American elm develops some of the characteristics of the English elm

Woodruff[59] has pointed out one marked case of adaptation to climate

The shape and size of the nose and position of the nostrils are now fairly well proved to be a matter of selection of fittest variations In the tropics where the air is hot and therefore rarefied, more of it is necessary and it is essential that there should be no impediment to the air currents, so that the nostrils are open and wide and the nose very flat Such a nose is unsuited for cold countries, as it permits masses of cold air to flood the air passages and irritate the lining membrane, so that the nose must be large and have much warming surface, and the nostrils therefore are slender slits to admit the air in thin ribbons easily warmed The air being cold is concentrated, and less of it is needed than in the tropics and the slender nostril is no disadvantage. The nasal index or extreme width of nose divided by the extreme length, gradually increases as we go to colder countries, where we find some races with nose index much greater than one thousand, *i e*, width greater than length. It is now many years since it was first pointed out that the open tropical nostril was one reason for so much pulmonary trouble of negroes out of tropics. Hence there must have been a natural selection in cold countries of one kind of variations—large concentrated noses, and a selection in hot countries

[56] "The Survival of the Unlike," 319, 1898

of the other extreme, so that the various types gradually arose.

The great Biblical Pharaoh Rameses II had a prominent, slender nose not now found in any Egyptians, and it is a positive proof of the recent arrival of some ancestor from the north. He was like Lord Cromer—a northern type ruling a native type.

Allen[60] has called attention to a correlation between climate and the color of birds.

The increase in color towards the south coincides with the increase in the intensity of the sun's rays and in the humidity of the climate. The increase in color observed in birds on passing from east to west [in the United States] seems also to coincide with an increase of humidity, "the darker representatives of any species occurring where the annual rainfall is greatest, and the palest where it is least." This coincidence occurs not only in the birds of the United States to such a degree that Allen says he knows of no exception, but in Europe also. Thus birds from the Scandinavian coast are very much darker than in central Europe, where the rainfall is only half as great. Allen says that this correlation of brighter and deeper tint with increased humidity is exhibited by the mammals of these districts as well as by the birds.

NON-ADAPTABILITY

While the theorem of Le Chatelier enables us to account for the direction of a change, it does not tell us whether a given stimulus will actually produce a change or under what condition the change will be a maximum for the same stimulus. We can make a fair guess at the answer by studying ourselves. We know that, as we get older, our tendency to resist change increases; our habits of body and mind become more fixed. We should therefore be tempted to conclude that the resistance to change increases as the organism becomes mature and that a given stimulus would probably have the most effect if applied at or before the earliest stages of development. The following quotation from Vernon[61] would seem to indicate that this was often true.

Due reflection, will, I believe, incline one to infer that what is true for echinoid larvæ is true for most multicellular organisms. In fact, it would seem to be a law of general application that *the permanent effect of environment on the growth of a developing organism diminishes rapidly and regularly from the time of impregnation onwards.*

It is curious that this principle, enunciated by the author in 1900, should have been laid down by De Vries only a few months later, as the result of his observations on plants. Thus, judging from the effects of nutrition (manuring, planting out, good light and watering), he concluded that (1) the younger a plant is, so much the greater is the influence of external conditions on its variability. (2) The nutrition of the seed, when developing on the maternal plant, has—at least very often—a greater influence on the variability than nutrition during its germination and later growth.

If the pressure on a liquid is made less than the vapor pressure for that liquid at that temperature, some of the liquid vaporizes, the temperature falls, and the liquid may be said to adapt itself to the new conditions. What would happen if the liquid were not adaptable? The easiest way to obtain a non-adaptable liquid is to place a Bunsen burner under it. The temperature rises until the boiling-point is reached. The liquid then ceases to be adaptable. It volatilizes, it disappears, it becomes extinct so far as that particular region or flask is concerned. If a species can not adapt itself to changed climate or other conditions, it does not volatilize, but it disappears, it becomes extinct. It may be a new point of view to consider the extinction of the mastodon as analogous to the distillation of water; but the two cases are really parallel, except in time.

It should be kept in mind that non-adaptability is not the only cause for ex-

[60] Vernon, "Variations in Plants and Animals," 327, 1903.

[61] "Variation in Animals and Plants," 199, 1903.

tinction. A species might have enormous potential adaptability, but it would become extinct if the death-rate were too high in comparison with the rate of adaptation. This principle is made use of in the fight against weeds:[62]

Weeds, like other plants, grow where they can find room, and the more room any plant can find, other things being the same, the farther and more rapidly it will spread over the earth. But room, used in this connection, does not mean, entirely, space vacant of other plants, but rather conditions of competition into which the given plant can fit itself with prosperity. Ground may be covered with a given plant, and yet a species of wholly different character and habits may thrive along with it. This is well illustrated in the growth of twining or climbing vines in dense thickets of shrubbery, or the practise, common even with the Indians, of growing pumpkins in corn fields. If weeds, then, are to be kept out of grounds, the land must not only be occupied with some other crops, but with a crop which will not allow the weed to grow along with it. In practise, it is impossible to select all crops from plants which so completely encumber the ground that no intruder can find a foothold; but this disadvantage is readily and almost wholly overcome by means of the rotation of crops—one crop in the rotation destroying what weeds may have crept in with the preceding ones. Thorough cropping of the land and judicious rotation of crops, therefore, are conditions against which no weeds can stand; and as these are the vital conditions, also, of successful agriculture, it may be said that then lands are well farmed.

The daisy-cursed meadows of the east are those which have been long mown and are badly "run," or else those which were not properly made, and the grass obtained but a poor start. The farmer may say that the daisies have "run out" the grass, but the fact is that the meadow began to fail, and the daisies quickly seized upon the opportunity to gain a foothold; and just so long as the farmer persists in his accustomed methods will the daisies usurp the land. The weedy lawns are those which have a thin turf, and the best treatment is to scratch the ground lightly with an iron-toothed rake, apply fertilizer and sow more seed; in other words, augment the struggle for existence, and the weeds will go down before the June grass, and the grass plants themselves, because of the greater numbers, will be more slender and will make a softer turf.

[62] Cf. Bailey, "The Survival of the Unlike," 194, 198, 1896.

ATTITUDE OF BIOLOGISTS

It may be asked to what extent biologists make use of the theorem of Le Chatelier as a working hypothesis in studying the effect of external conditions. So far as I can learn, nobody makes any active use of it, and many biologists would deny the applicability of the theorem.

Darwin[63] began by attributing very little to the direct action of the climate, etc.; but later he stated that more weight should have been allowed to the direct action of the environment, *i. e.*, food, climate, etc., independently of natural selection. He says[64] that it is "probable that variability is directly or indirectly caused by changed conditions of life. Or, to put the case under another point of view, if it were possible to expose all the individuals of a species during many generations to absolutely uniform conditions of life, there would be no variability." In spite of this he states[65] explicitly that long-continued action of a different climate has produced differences in American trees which are of no especial service to them.

Nägeli's[66] "extensive cultural experiments with alpine *Hieracia* led him to form the opinion that the changes which are induced by an alteration in the food-supply, in climate or in habitat, are not inherited and are therefore of no importance from the point of view of the production of species."

[63] Cf. Schwalbe, "Darwin and Modern Science," 125, 1909.

[64] Darwin, "Animals and Plants under Domestication," 2d ed., 2, 242, 1890.

[65] Darwin, "Animals and Plants under Domestication," 2d ed., 2, 271, 1890.

[66] Cf. Klebs, "Darwin and Modern Science," 225, 1909.

De Vries[67] is distinctly not prepared to admit that mutations are described by the theorem of Le Chatelier.

The origin of new species, which is in part the effect of mutability, is, however, due mainly to natural selection. Mutability provides the new characters and new elementary species. Natural selection, on the other hand, decides what is to live and what to die. Mutability seems to be free, and not restricted to previously determined lines. Selection, however, may take place along the same main lines in the course of long geological epochs, thus directing the development of large branches of the animal and vegetable kingdom. In natural selection it is evident that nutrition and environment are the main factors. But it is probable that, while nutrition may be one of the main causes of mutability, environment may play the chief part in the decisions ascribed to natural selection. Relations to neighboring plants and to injurious or useful animals, have been considered the most important determining factors ever since the time when Darwin pointed out their prevailing influence.

There is nothing very definite to be obtained from Klebs.[68]

The dependence of *variable internal* on *variable external* condition gives us the key with which research may open the door. In the lower plants this dependence is at once apparent, each cell is directly subject to external influences. In the higher plants with their different organs, these influences were transmitted to cells in course of development along exceedingly complex lines. In the case of the growing point of a bud, which is capable of producing a complete plant, direct influences play a much less important part than those exerted through other organs, particularly through the roots and leaves, which are essential in nutrition. These correlations, as we may call them, are of the greatest importance as aids to an understanding of form production. When a bud is produced on a particular part of a plant, it undergoes internal modifications induced by the influence of other organs, the activity of which is governed by the environment, and as the result of this it develops along a certain direction; it may, for example, become a flower. The particular direction of development is determined before the rudiment is differentiated and is exerted so strongly that further development ensues without interruption, even though the external conditions vary considerably and exert a positively inimical influence: this produces the impression that development proceeds entirely independently of the outer world. The wide spread belief that such independence exists is very premature and at all events unproven.

The state of the young rudiment is the outcome of previous influences of the external world communicated through other organs. Experiments show that in certain cases, if the efficiency of roots and leaves as organs concerned with nutrition is interfered with, the production of flowers is affected, and their characters, which are normally very constant, undergo far-reaching modifications. To find the right moment at which to make the necessary alteration in the environment is indeed difficult and in many cases not yet possible. This is especially the case with fertilized eggs, which in a higher degree than buds have acquired, through parental influences, an apparently fixed internal organization, and this seems to have predetermined their development. It is, however, highly probable that it will be possible, by influencing the parents, to alter the internal organization and to switch off development on to other lines.

Bailey is quite clear that the environment has a marked effect upon plants, but he is very far from formulating that effect, as the following quotations will show.[69]

These differences [between individual plants] arise as a result of every impinging force, soil, weather, climate, food, training, conflict with fellows, the strain and stress of wind and wave, and insect visitors, as a complex resultant of many antecedent external forces, the effects of crossing, and also as the result of the accumulated force of mere growth; they are indefinite, non-designed, an expression of all the various influences to which the passive vegetable organism is or has been exposed; these differences which are most unlike their fellows or their parents find the places of least conflict and persist because they thrive best, and thereby impress themselves best upon their offspring.

It is not too much to ask of climatology that it shall tell us why the northern climates develop saccharine elements and high colors, and why the

[67] "Darwin and Modern Science," 77, 1909.

[68] "Darwin and Modern Science," 223, 236, 242, 1909.

[69] Bailey, "The Survival of the Unlike," 32, 309, 1896.

Wisconsin-Minnesota area produces such remarkable waxen and pruinose tints. The influence of the climate is nowhere so easily traced, perhaps, as in the business of seed growing. Every seedsman knows that certain climates are not only best adapted to growth of certain seed crops, but that they exert a profound influence upon the character of the product grown by them. The study of all these interrelations of climate and plant life falls into three subjects: phenology, or the study of the periodic phenomena of plants, a subject which loses half its value when considered, as it usually is, without reference to the visible attending features of climate; acclimatization, or a consideration of the means by which plants adapt themselves to climates at first injurious, and secondary variations of plants induced by climate environment.

The burden of my plea is twofold. First, while not discouraging the instrumental or conventional study of climate, I would encourage its study in terms of plant life. Second, it is essential that the synchronisms of local climate and the phenomena of plants be given the closest attention.

Sedgwick[70] is quite clear as to the direction of the changes, but I can not see that he makes any actual use of this as a working hypothesis.

It is a property of living matter to react in a remarkable way to external forces without undergoing destruction. The life-cycle, of which the embryonic and larval periods are a part, consists of the orderly interaction between the organism and its environment. The action of environment produces certain morphological changes in its organism. These changes enable the organism to come into what is practically a new environment, which in its turn produces further structural changes in the organism. These in turn enable, indeed necessitate, the organism to move again into a new environment, and so the process continues until the structural changes are of such a nature that the organism is unable to adapt itself to the environment in which it finds itself. The essential condition of success in this process is that the organism should always shift into the environment to which the new structure is suited—any failure in this leading to the impairment of the organism. In most cases the shifting of the environment is a very gradual process (whether consisting in the very slight and gradual alteration in the relation of the embryo as a whole to the egg-shell or uterine wall, or in the relations of its parts to each other, or in the successive phases of adult life), and the morphological changes in connection with each step of it are but slight. But in some cases jumps are made such as we find in the phenomena known as hatching, birth and metamorphosis. This property of reacting to the environment without undergoing destruction is, as has been stated, a fundamental property of organisms. It is impossible to conceive of any matter to which the term living could be applied being without it. And with this property of reacting to the environment goes the further property of undergoing a change which alters the relation of the organism to the old environment and places it in a new environment.

This quotation is not what we want, because Sedgwick is considering the life cycle of an individual, which is not our problem at all. It is good as far as it goes, however, and it is the best that I have been able to find.[71]

We get the opposite extreme with Bateson,[72] who says:

To those who have made no study of heredity it sometimes appears that the question of the effect of conditions in causing variation is one which we should immediately investigate, but a little thought will show that before any critical inquiry into such possibilities can be attempted, a knowledge of the working of heredity under conditions as far as possible uniform must be obtained.

The cap seems to fit and I am quite ready to put it on. Bateson's argument is simply that a change due to reversion might be interpreted as due to a change in environment. This is a possible source of error, but it is one which can be eliminated by making enough experiments and by making experiments with different species of plants. It is hardly conceivable that a reversion to an albino variety, for instance, should coincide with a given change of environment in every experiment and with every kind of plant. On the other hand,

[70] "Darwin and Modern Science," 177, 1909.

[71] Cf. also Bourne, Science, 32, 738, 1910.

[72] "Darwin and Modern Science," 95, 1909.

it is always a good plan to do the easiest things first, partly because it takes less time to get results, but chiefly because the easy things usually throw light on the hard ones. We know that suitable changes in the environment, if made at a suitable time, will cause such changes in the organism that the next generation differs from the first. It is a very difficult problem to determine the intermediate steps; but it is a relatively simple one to determine what change in the second generation is the result of a change in a single factor of the environment This is a problem which has not been attacked by the biologist in any systematic fashion, and it is a problem which will be greatly simplified by an intelligent application of the theorem of Le Chatelier.

The view of the biologists seems to be that each generation always varies spontaneously from the preceding one to a greater or lesser extent, and that these variations are reproduced more or less completely in the succeeding generation. By the survival of the fittest we eventually get a race which is better adapted to the local conditions than the one from which we started.

The view that I have outlined is that the external conditions tend to produce such changes in the organism that the next generation varies in such a way as to be more adapted to local conditions. By the survival of the fittest and by the continued action of the external conditions, we eventually get a race which is better adapted to the local conditions than the one from which we started

We reach the same conclusion whichever way we consider the matter. The two views are not mutually exclusive because it is quite possible to consider the variation due to the external conditions as superimposed on the spontaneous variations. If we are to decide between the two points of view, it must be on other grounds than qualitative results. To me, the phrase "spontaneous variation" seems merely another way of expressing our ignorance I do not believe in a variation without a cause If we go back far enough, all variations must be the result of varying external conditions and the real problem is to show what part of any given variation in any given organism is due to the effect of external conditions on the preceding generation and what part is due to the effect of external conditions on still earlier generations. What we study under heredity, as the word is usually used, is the transmitted effect of varying external conditions upon the more or less remote ancestors

Another objection to the biologist's point of view is that it has not worked out well practically Being obsessed by the idea of spontaneous variation, he has very rarely taken the trouble to work out carefully the relation between each particular factor of the external conditions and the acquired characteristics of the organism which has become better adapted to its surroundings If the biologist had had the theorem of Le Chatelier as a guiding hypothesis, he would not have made this mistake and he would often have done better and more careful work.

I have tried to show that the theorem of Le Chatelier is a universal law and that it is consequently of great value in enabling us to correlate old facts and to discover new ones

THE SEVENTEENTH INTERNATIONAL CONGRESS OF AMERICANISTS

The second session of the seventeenth International Congress of Americanists was held

in the Museo Nacional, Mexico City, Mexico, September 8–14, 1910.[1] In addition to Mexico, the following countries were represented by official delegates present. Austria-Hungary, China, Costa Rica, Cuba, France, Germany, Guatemala, Holland, Italy, Japan, Portugal, Salvador, Spain and the United States of America There were also in attendance delegates from a number of learned societies and other institutions from various parts of the world

The United States government was represented by Professor Franz Boas, Professor Roland B. Dixon, Dr Aleš Hrdlička and Dr Alfred M. Tozzer. The state of Louisiana was represented by Judge Joseph A Breaux Delegates from several American institutions were present Drs. Pliny E. Goddard and Herbert J Spinden, American Museum of Natural History, Mr. Stansbury Hagar, Brooklyn Institute of Arts and Sciences; Mr. William Beer, Howard Memorial Library; Mrs. Zelia Nuttall, University of California; Professor George B Gordon, University of Pennsylvania; and Dr. George Grant MacCurdy, Yale University. All these are members of the American Anthropological Association

To any one interested in American archeology Mexico offers remarkable attractions, not only in the priceless treasures of the Museo Nacional, but also in the number and grandeur of the prehistoric ruins The author spent five weeks in excursions to various sites, and in study at the museum. His program was no doubt duplicated by many other visiting members. The only official excursions announced by the committee of organization were those to Teotihuacan, Mitla and Xochicalco. The first of these took place during the congress To it were invited not only the members of the Americanist Congress but also the official delegates to the Mexican centenary, the hosts being the department of foreign affairs as well as that of public instruction and fine arts. It was made the occasion for the opening of the new museum at the ruins of Teotihuacan. An elaborate dinner was served in the celebrated grotto near the Pyramid of the Sun, at which speeches were made by both the secretary of foreign affairs, Señor Creel, and the secretary of public instruction and fine arts, Señor Sierra. The excursions to Mitla and Xochicalco took place after the congress and were unfortunately marred by some confusion and delay.

Among the centennial attractions that were of special interest to the Americanists was the great historic pageant occurring the day after the congress closed The first section of the pageant numbering 889 persons, dealt with the epoch of the conquest, particularly the first meeting between Montezuma and Cortes (1519). The sections which followed represented the epochs of Spanish dominion and of independence, respectively

There were a number of special social functions in honor of the congress, including receptions by the minister of public instruction and fine arts, and by Mrs Zelia Nuttall at her interesting home, Casa Alvarado, in the historic old suburb of Coyoacan.

The mode of selection of the council emphasized a weakness of the statutes that should be remedied by amendment at the next congress So far as I have been able to ascertain, no change has been made in the statutes since the close of the first congress[2] Article 7 of the statutes is as follows:

> The Assembly elects the Members of the Council of which the number is determined by the Committee of Organization.
>
> Each nationality should, at all events, be represented by at least one Member.

This article gives the committee of organization power to limit the number of the council and thus in a measure to determine its personnel. By its very nature the committee of organization is temporary and a local body; while the congress itself is international. Not a single member, for example, of the committee of organization of the immediately preceding congress in Vienna was on the com-

[1] A session had already been held in Buenos Aires during the month of May.

[2] Congrès intern. des Americanistes, Compte rendu de la première session, t. II., p. 170, Nancy, 1875.

mittee of organization of the congress in Mexico. The latter committee decided to limit the council to governmental delegates. In doing so it took into the council diplomats and the judge of a state court, excellent men all of them, but only momentarily interested in the purposes for which the congress exists At the same time it left out of the council those who have been attending the congresses for years, some of whom had previously sat in its councils, and including professional Americanists attached to and delegated by some of the foremost museums and institutions of learning in America. If the last paragraph of article 7 can be construed in such a manner as to take the control of the congress away from those, but for whom it could not exist, it should be amended at the first opportunity, and the power to limit the number of the council should be transferred from the ephemeral committee of organization, often composed of members who never attended a congress before and who will probably never do so again, to the "Assembly" of members present, which in a measure, at least, is a perpetual body

During the congress, a committee of delegates from Mexico, France, Germany, Harvard University, the University of Pennsylvania and Columbia University met and agreed upon the foundation of an international school of archeology in the city of Mexico. Other governments and universities may take part in this movement by subscribing to the by-laws (now in process of ratification). The present director of the school is Professor Eduard Seler.

The next congress will be held in London during the month of September, 1912.

The following papers were presented and will be published in the *Compte rendu* of the congress:

"La etnología de las razas indígenas que poblaron las comarcas del sur de Tamaulipas," Alejandro Prieto.

"Contribution to the Anthropology of Peru," Aleš Hrdlička.

"La huella más antigua quizá del hombre en la península de Yucatan; Estudio de la industria prehistórica de Concepción (Campeche)," Jorge Engerrand.

"Pruebas geológicas de que la parte norte de la peninsula yucateca no ha podido ser habitada por el hombre durante la época cuaternaria," Jorge Engerrand.

"Un caso de cruzamiento entre un Chino y una Yucateca de origen indígena," Jorge Engerrand.

"Quelques observations sur l'art de guerir chez certains tribus nomades du nord du Mexique," Theo. Dupoyet[1]

"La trepanacion entre nuestros aborígenes," Alberto M Carreño

"El rayo de luz y la cronología india," Abraham Castellanos

"Sobre correcciones del período de Venus en los manuscritos historicos mexicanos," Hermann Beyer[1]

"Zodiacal Symbolism of the Mexican and Maya Month- and Day-signs," Stansbury Hagar

"The Celestial Plan of Teotihuacán," Stansbury Hagar

"El zodiaco de los Incas en comparacion con el de los Aztecas," Arnolfo Krum Heller

"Los grandes ciclos de la historia maya según el manuscrito del Chumayel," Juan Martinez Hernandez

"La medicina entre los Indios mexicanos antes de la conquista," Francisco A. Flores.

"Publicaciones nuevas sobre la linguistica americana," Franz Boas.

"A Classification of Maya Verbs," Alfred M. Tozzer.

"Lenguas de la familia nahuatlana; su clasificacion," Francisco Belmar.

"Dios ¿Que idea tenian de el los antiguos mexicanos?" Cecilio A. Robelo[1]

"Idolatrias y supersticiones de los Indios," Vicente de P. Andrade.

"El verdadero concepto de la etnología: La ciencia de gobernar," Andres Molina Enríquez (read by title).

"Algunas lenguas que se hablan en el sur del Estado de Chiapas," Carlos Sapper.[1]

"The Language of the Tano Indians of New Mexico," John P. Harrington.[1]

"Colon y la lengua castellana y las americanas," Antonio Sánchez Moguel.

[1] Read by title, but will be published in the *Compte rendu* of the congress.

"Itinerario de la expedición de Hernán Cortés á Hibueras," Marcos E. Becerra[*]

"El testamento de Hernán Cortés," Francisco Fernández del Castillo

"Une mappe inédite de 1534, avec texte espagnol au verso," Louis Capitan

"L'œuvre géographique de Humboldt en Mexique," Eugen Oberhummer

"Les observations géographiques dans les lettres de Cortes," Eugen Oberhummer[*]

"Resumen de mis estudios de documentos del siglo XV contenidos en el Archivo General y Público de la Nacion," Zelia Nuttall.

"Algunos de los primeros establecimientos de instrucción en el Reino de Nueva Galicia," Francisco Escudero[*]

"Estudio geografico, historico, etnografico y arqueologico de la Republica de El Salvador," Leopoldo A. Rodríguez

"Breves notas sobre la historia, la arqueología y la etnogenia del territorio de Tepic," Francisco A. Flores

"Notes sur le Mexique," Auguste Genin.[*]

"A Manuscript in Washington," Charles Warren Currier[*]

"El Votan," Enrique Santibanez

"Photographic Notes on the Pueblo Indians of Southwestern United States," Frederick I. Monsen[*]

"Estudio sobre la teoria del origen oriental de algunas razas americanas," Manuel Cortes[*]

"Chronological Sequence of the Sculptures of Copan," Herbert J. Spinden

"Sobre algunas representaciones del dios Huitzilopochtli," Hermann Beyer[*]

"Une figuration de Quetzalcoatl sous forme de serpent emplumé enroulé, provenant de Mexico," Louis Capitan

"La stylisation de la figure humaine et la représentation des sacrifices humains sur les vases peints preincasiques de Vazca (Pérou)," Louis Capitan

"Miniature Clay Temples of Ancient Mexico," H. Newell Wardle

"An Aztec 'Calendar Stone' in the Yale University Museum," George Grant MacCurdy

"Elements of Kato, an Athabascan Dialect," Pliny E. Goddard.

"Las ruinas de Uxmal," Eduardo Seler

[*] Read by title, but will be published in the *Compte rendu* of the congress.

"The Ruins of Northeastern Guatemala," Alfred M. Tozzer

"Un dato sobre la evolución del alfabeto entre los azteca y los maya," Jesús Díaz de León

"La reparacion de las ruinas de Xochicalco," Leopoldo Batres

"Estudio comparativo de dos documentos historicos," Antonio García Cubas[*]

"Some Points in Louisiana Cartography," William Beer

"Three Centuries of Total Eclipses of the Sun in Mexico. 1850–2150," David Todd[*]

"Central and South America—Governmental Cooperation the Key to Great Opportunity," Louis E. Walkins[*]

"Résumé of the Papers, read at the Sixteenth Congress held at Vienna, on Mexican History, Architecture, Art, etc." Franz Heger.

GEORGE GRANT MACCURDY

YALE UNIVERSITY,
NEW HAVEN, CONN.

THE NEW PLAN FOR ADMISSION TO HARVARD UNIVERSITY

ON January 17 the Faculty of Arts and Sciences of Harvard University voted to adopt the plan of admission as given below as an alternative to the system at present in force. The plan, it will be noted, is a compromise between the certificate and examination methods. It is intended to obviate "cramming" for examinations and to improve articulation with secondary schools, especially public high schools.

A. Evidence of the completion of an approved secondary school course.

1. Tabulated statement. A candidate shall present to the committee appointed to administer this plan evidence as to his secondary school work in the form of an official detailed statement showing (*a*) The subjects studied by him and the ground covered. (*b*) The amount of time devoted to each. (*c*) The quality of his work in each subject.

2. Approved school course. An "approved secondary school course" must (*a*) extend over four years, (*b*) concern itself chiefly with languages, science, mathematics and history. No one of these four subjects may be omitted. At least two studies of a candidate's school program must be carried to the stage required by the present advanced examinations of Harvard College, or by

the equivalent examinations of the College Entrance Examination Board

B. Examination in four subjects

1 Subjects. A candidate who presents evidence that he has satisfactorily completed an "approved secondary school course," shall offer himself for examination in the four subjects named below. A satisfactory record in these examinations shall admit to Harvard College without conditions (a) English, (b) Latin, or for candidates for the degree of S.B., French or German, (c) Mathematics, or Science (Physics or Chemistry), (d) any subject (not already selected under (b) or (c) from the following list. Greek, French, German, History, Mathematics, Chemistry, Physics

2 The examination papers (a) The preparation presupposed by the examination papers in the several subjects shall not be less than is ordinarily necessary for the present elementary examinations The papers shall contain a sufficient number of alternative questions, and shall be so framed as to permit variety in the methods of school instruction They shall also include advanced questions, thus permitting each student to reveal the full amount and the quality of his attainment. In any subject offered for examination which the candidate has pursued to an advanced grade he must present evidence of that grade of attainment The papers shall not, however, presuppose a greater length of preparation than is ordinarily required for the present Harvard examinations (b) Time of examinations. The four examinations must be taken at one time, in either June or September (c) Judging the examination books A copy of the candidate's school record shall be given to the readers of the examinations In judging the books the examiner shall submit a full statement of his opinion of each book. In addition, at the option of the examiner, a grade may be given

3. A satisfactory record. A "satisfactory record" shall not be construed to require that a candidate attain distinction in all four subjects, but shall mean that in the judgment of the Committee on Admission the candidate's examination record as a whole, when viewed as the basis for a general estimate of his quality, is such as to make his admission to Harvard College advisable

THE NEW YORK ZOOLOGICAL SOCIETY

THE seventeenth annual meeting of the New York Zoological Society was held at the Hotel Waldorf-Astoria, January 10, 1911, at 8 30 o'clock P.M. Mr. Henry Fairfield Osborn, president of the society, presided and Mr. Madison Grant, the chairman of the executive committee, laid before the meeting the report of that committee for the year 1910. Colonel C. J Jones gave the first public exhibition of a series of moving pictures showing the roping and capture of living wild animals in British East Africa, including lions, rhinoceroses and various antelopes, and Mr. Roy C. Andrews showed a series of pictures taken during the past season of the capture of whales in Japanese waters.

The report of the executive committee covered the following matters

During the year $12,848 have been expended for the purchase of animals, chiefly for the purpose of strengthening the collections in general, from a zoological point of view, rather than for the purchase of costly special features As a result of this policy, the collections, as a whole, are to-day stronger in rare species, and also in number of individuals, than at any previous period. The health of the collections at the park and the aquarium has been maintained at a high standard throughout the year, and there have been few losses of importance

Administration Building.—The administration building was completed and thrown open to the use of the members on November 20, 1910. It provides accommodations for the members of the society, and it is hoped that members and their guests will make full use of the opportunities afforded.

New Buildings.—The following new structures are under way at the present time: Ten additional bear dens and cages, eagles and vultures aviary, and a winter house for tropical birds of prey. Plans for a zebra house have been completed, and the contract, it is hoped, will be awarded during the winter.

National Collection of Heads and Horns.—The National Collection of Heads and Horns has been greatly increased during the year and now contains 688 specimens A few of the most notable additions are: Head of square-mouthed rhinoceros from Col. Theodore Roosevelt; bongo, from Mr. James L. Clark; New Brunswick moose, from Mr

Edwin C. Kent, and the following heads from Mr. H. Casimir de Rham: Karelin sheep, Turkestan sheep, Astor markhor, two Himalayan ibex, Quchim buffalo, Newfoundland caribou, musk ox and sable antelope.

Library.—The administration building will also contain the library, which now numbers 1,378 volumes. A fund of $2,000 was provided by two of the friends of the society for this purpose.

Gifts.—Among the most notable gifts have been a remarkable series of arctic animals from Mr. Paul J. Rainey, as follows: Six musk ox, two walrus, two polar bears, one blue fox.

Pheasant Expedition.—The New York Zoological Society expedition for pheasants is now in Siam, and is expected to return to New York some time during the summer of 1911. The expedition has been successful in securing specimens, living and dead, of nearly all the pheasants in the districts visited.

Aquarium.—The New York Aquarium has, in its present building, nearly reached the limit of its capacity both for its collections and for visitors. The enormous attendance makes it necessary to provide a larger and more modern building, and several studies of plans for this purpose have been made. The city will be asked to provide the necessary funds for the new aquarium.

SCIENTIFIC NOTES AND NEWS

SIR FRANCIS GALTON, eminent for his contributions to geography, meteorology, biology, anthropology and psychology, died on January 18, at the age of eighty-eight years.

AT the annual meeting of the trustees of the Carnegie Institution of Washington, Dr. Simon Flexner, of the Rockefeller Institute of Medical Research, Mr. Robert S. Brookings, of St. Louis, and Dr. Henry Pickering Walcott, of Boston, were elected to membership in the board.

SIR JOHN MURRAY will give a memorial address on "The Life and Scientific Works of Alexander Agassiz," at Sanders Theater, Harvard University, on Tuesday evening, February 14.

THE next Faraday lecture of the Chemical Society of London is to be given on June 14 by Professor Theodore W. Richards, of Harvard University, in Faraday's lecture-room at the Royal Institution on Albemarle Street, London.

DR. JACQUES LOEB, of the Rockefeller Institute for Medical Research, has been elected an associate of the Royal Academy of Science at Belgium, in the section of natural science; and also an honorary foreign member of the Academy of Medicine of Belgium.

DR. ALEŠ HRDLIČKA has been made a corresponding member of the Academy of Sciences, Prague.

SIR DAVID GILL has been elected a foreign member of the Swedish Royal Academy of Sciences, Stockholm.

M. EDOUARD BRANLY has been elected a member of the Paris Academy of Sciences in the section of chemistry. He received thirty votes, twenty-eight votes being cast for Madame Curie.

DR. DAVID FERRIER, F.R.S., emeritus professor of neuropathology in King's College, London, has been knighted.

PROFESSOR M. E. COOLEY, dean of the department of engineering of the University of Michigan, was given the degree of doctor of engineering by the University of Nebraska on January 18.

THE Geological Society of London will this year award its medals and funds as follows: The Wollaston Medal to Professor Waldemar C. Brögger, Sc.D.; the Murchison Medal to Mr. Richard H. Tiddeman, M.A.; the Lyell Medal to Dr. Francis A. Bather, M.A., and Dr. Arthur W. Rowe; the Bigsby Medal to Dr. O. Abel; the Wollaston Fund to Professor O. T. Jones, M.A.; the Murchison Fund to Mr. Edgar S. Cobbold; the Lyell Fund to Professor Charles G. Cullis, D.Sc., and Mr. John F. N. Green.

ADDITIONAL grants have been made to Professor T. W. Richards and to Professor G. P. Baxter, of Harvard University, of $2,500 and

$1,000, respectively, as research associates of the Carnegie Institution of Washington.

DR. G. CARL HUBER, professor of histology and embryology in the department of medicine of the University of Michigan, has tendered his resignation as secretary. Dr Huber has been made head of the new department of embryology at the Wistar Institute of Anatomy, Philadelphia, and will spend part of his time there An arrangement has been effected for the next two years By long service Dr. Huber has earned a year's leave of absence, which the regents have consented to allow in two periods of six months each. During the next semester Dr. Huber will be at the Wistar Institute, and he will return to the University of Michigan for the first semester of next year Dr C W Edmunds, professor of therapeutics and materia medica, has been elected secretary of the department

PROFESSOR R. A HARPER, head of the department of botany at the University of Wisconsin, has left for the University of California, where he will lecture during the remainder of the present academic year. Professor George J. Pierce, of Stanford University, will be acting professor of botany at the University of Wisconsin.

DR. ARTHUR W. WEYSSE, professor of biology at Boston University, has started on a trip around the world on sabbatical leave of absence. He will sail from San Francisco on February 8, for Hawaii and Japan, and will be away about eight months.

ON January 20 Professor Arthur Michael lectured before the members and research students at the department of chemistry at Clark University on his recent observations in connection with reversible organic chemistry. A result of the greatest importance is Professor Michael's discovery of an apparently new factor influencing the velocity of organic reactions.

DR. GEORGE T. MOORE, of the Shaw Botanical Gardens at St. Louis, gave a public lecture before the Society of Sigma Xi, of Cornell University, on January 17, on "Some Striking Advances in Botanical Science and the Application of these in Practical Affairs."

ON January 18 Professor A E. Kennelly, of Harvard University, delivered a lecture before the Society of Sigma Xi at the University of Pennsylvania on "Wireless Telegraphy and Telephony as compared with Wire Telegraphy and Telephony."

A SPECIAL meeting of the Geological Conference was held at Harvard University on January 31, when Mr. Frank A Perret, of Naples, Italy, spoke on "Volcanoes and Volcanic Action," with illustrations Mr. Perret has spent the last six years in the study of volcanic problems, and has lived on Vesuvius, Etna and Stromboli during their recent eruptions

AT a general meeting of the Association of Public School Science Masters held in London on January 11 and 12, the president, Sir Edwin Ray Lankester delivered an address on "Compulsory Science *versus* Compulsory Greek"

AT a meeting of the Royal Geographical Society on January 16 Dr Johan Hjort gave a detailed account of the Michael Sars North Atlantic deep sea expedition of 1910, which he, with Professor H. H. Grau, Dr. Helland-Hansen, Mr. E Koefoed, and Captain Thor Iversen, undertook at the suggestion and at the expense of Sir John Murray, who himself accompanied them.

UNIVERSITY AND EDUCATIONAL NEWS

THE General Education Board has made conditional appropriations as follows: Brown University, $100,000; Carleton College, $100,000; Colorado College, $50,000; Dakota Wesleyan University, $50,000; Denison University, $75,000; Fisk University, $60,000; Mount Holyoke College, $100,000; Randolph-Macon College, $50,000; Swarthmore College, $75,000, Wesleyan College for Women, $50,000.

THE bill increasing the annual appropriation from the state of Vermont to Middlebury College by $7,600 has been signed by Governor Mead. This will make the state appropriation to Middlebury $16,000 a year, beginning on July 1. The increase is "to provide additional instruction in the departments

of pedagogy, in forestry and in scientific branches related to the industries of Vermont."

A GIFT of $50,000 to Cornell University by Mrs Florence O. R. Lang, of Montclair, N J., will be used in the construction of a new building to house the shops of the Sibley College of Mechanical Engineering.

THE will of Octavia Williams Bates, of Baltimore, leaves to the library of the department of law of the University of Michigan, a bequest of $20,000 A bequest of $5,000 is made to the Detroit High School Scholarship Fund Association, an organization designed to lend money to graduates of the Central High School of Detroit, so that they may attend the university A number of other legacies for private and public purposes are provided. When all these are settled, the remainder of the estate is to go to the University of Michigan Miss Bates was a graduate of the literary department of the university in 1877, and of the law in 1896

DR. A M HILTEBEITEL has been appointed instructor in mathematics at the University of Pennsylvania. Dr H. B. Smith has been appointed instructor in the same department for the ensuing term, to fill the vacancy caused by the temporary absence of Professor Evans

AT the Massachusetts Agricultural College Dr. Guy Chester Crampton has been appointed associate professor of entomology. Dr. Crampton is a native of Alabama. He graduated from Princeton in 1904, took two years of graduate work at Cornell University, receiving his M A there in 1905, followed by two years at the universities of Freiburg, Munich and Berlin, where he received his Ph.D in 1908. He was an instructor in biology at Princeton from 1908 to 1910 and since the summer of 1910 has been professor of zoology at Clemson College.

DISCUSSION AND CORRESPONDENCE

NUMERICAL NOMENCLATURE

THE recent proposal of Professor James G. Needham[1] to use numbers and symbols as aids in zoological nomenclature, which has been sympathetically discussed by Professor Henry B. Ward[2] and destructively criticised by Professor T. D. A Cockerell[3] in the columns of SCIENCE, has reminded me that one of the earliest attempts at entomological classification employed the numerical method which Professor Needham appears to think likely to prove useful In the year 1766 (one hundred and forty-five years ago) the Rev. Jacob Christian Schaeffer, D D, began the publication of an illustrated work upon the insects found in the vicinity of Regensburg, his home, and brought it to a conclusion in the year 1779 The title of the work is given in Latin and German as follows· "Icones Insectorum circa Ratisbonam indigenorum coloribus naturam referentibus expressæ Natürlich ausgemahlte Abbildungen Regensburgischen Insecten" The indices of the several volumes show that they might have served as models for Professor Needham. Opening at random I find the following in volume I.:

[1] SCIENCE, N S, Vol XXXII, p. 295

[2] SCIENCE, N S, Vol. XXXIII, p. 25.

[3] SCIENCE, N S, Vol. XXXII., p. 428.

In volume III. we find *Hesperia malvæ* Linn. designated as the "Siebender sechsfüssiger Tagfalter mit schiefen Flugeln," etc.

"Verily, there is nothing new under the sun!"

For my part, I sympathize with all attempts to secure a fixed and simple system of nomenclature, but to revert to what were the methods of good old Dr. Jacob Christian Schaeffer in this twentieth century is not, in my opinion, the correct solution of our difficulties

The troubles of the student of nomenclature are not, I suspect, as great as they appear to be to those who do not possess the necessary apparatus of books and who have devoted more time to questions of morphology than to questions of taxonomy. I have not at present the leisure to take up the questions involved in this discussion as I should like to do, but simply wish to remind the readers of SCIENCE that the method of numerical designations was employed nearly a century and a half ago for an extensive fauna, and that the numbers for a good many species in various genera are therefore already "preoccupied"

W. J. HOLLAND

SCIENTIFIC BOOKS

Respiratory Calorimeters for Studying the Respiratory Exchange and Energy Transformations of Man By FRANCIS G. BENEDICT and THORNE M. CARPENTER Published by the Carnegie Institution of Washington. 1910. Pp. 210.

This contains a full description of the latest models of respiratory calorimeters. Two are mentioned, the "chair calorimeter" designed for individuals for six- to eight-hour periods during which they can remain comfortably seated in a chair, and the "bed calorimeter" for use at night or for the sick or bed-ridden.

The measurements of heat eliminated by man as made by this apparatus are based upon the fact that the subject is enclosed in a heat-proof chamber through which a current of cold water is constantly passing. The amount of water is carefully weighed. The temperatures of the water entering and leaving the chamber are accurately recorded at frequent intervals The walls of the chamber are held adiabatic, thus preventing a gain or loss of heat. Thermo-electric couples connected with a galvanometer notify an observer of temperature changes of the walls. The observer then corrects this by arbitrarily cooling or heating the outer metal walls, a second cold water current accomplishing the former and electric wiring the latter, both systems being outside the inner chamber The heat given to the first described water current circulating within the inner chamber, is exactly equal to the heat eliminated by radiation and conduction by the subject To determine the total heat elimination, the latent heat of water vapor evaporated from the skin and lungs must also be added The sensitiveness of this apparatus is very great. Foreigners as well as fellow countrymen have pronounced it a wonderful machine. In addition to the determination of heat elimination, the carbonic acid outgo and oxygen ingo are determined through an accessory apparatus which provides for the analysis of the circulating air

The apparatus is costly in the first instance and requires many workers to control In the hands of Dr. Benedict it has received notable improvements, and it is both wise and fortunate that he has had the splendid generosity of the Carnegie Institution to support his undertaking

GRAHAM LUSK

The Metabolism and Energy Transformations of Healthy Man during Rest By FRANCIS G BENEDICT and THORNE M. CARPENTER. Published by the Carnegie Institution of Washington. 1910. Pp. 255.

This work contains a very valuable compilation of statistics obtained from observation on many normal men who had been occupants of the respiration-calorimeter of Atwater, Rosa and Benedict As a rule records of the protein metabolism are not recorded, which leaves an important gap unfilled The authors state that the work of Zuntz and others who used respiration apparatus of the Zuntz type is "as accurate as can be expected with apparatus of this type." The recently published work of Durig, how-

ever, shows that the results of oxygen absorption and carbondioxide elimination as determined by the Benedict calorimeter and the Zuntz apparatus are identical. There is therefore no doubt that the preeminent feature of the apparatus used by Benedict is the calorimetric determinations.

The authors find that the average heat production for fifty-five subjects during waking hours is 97.1 total calories, 1.52 per kilogram of body weight, and 49.2 per square meter of body surface, per hour. These records are 35 per cent above the requirements in sleep. Further experiments showed an average requirement of 17.8 additional calories when a subject undressed, weighed himself and dressed again. An important generalization is that the pulse rate is more or less parallel to the total metabolism.

This book suffers very greatly from a fault that has pervaded the publications of the Nutrition Laboratory, both at Boston and at Middletown, and that is that the new discoveries are not sharply defined as separate from well-known facts. This fault occurs in Benedict's splendid monograph on "Inanition" where the one new fact, the quantitative determination of the amount of glycogen oxidized on the first and second days of fasting is passed over without emphasis.

The authors make the following statement: "A striking series of experiments has demonstrated very clearly that a change from a diet poor in carbohydrates to one rich in carbohydrates is accompanied by a considerable retention of water by the tissues of the body." This however is not an original observation, having been noted by Bischoff and Voit, fifty years ago.

The world owes a great debt to the work of the Carnegie Nutrition Laboratory and its forerunner in Middletown, which no one can gainsay. Criticism is offered in the spirit of Pflüger who held it to be the mainspring of every advance and the Altmeister adds, "deshalb übe ich es."

GRAHAM LUSK

The Elements of the Theory of Algebraic Numbers. By L. B. REID. New York, The Macmillan Company. 1910. Pp. xix + 454.

The title of this book is misleading, as it treats of no algebraic numbers other than quadratic; it can not be said to present even the elements of the theory of algebraic numbers. The author devotes 150 pages to the elementary congruencial properties of rational numbers and 300 pages to quadratic numbers. In view of the intimate relations between quadratic forms and the numbers and ideals of a quadratic field, the omission of an account of quadratic forms is certainly a serious defect in a book having the aims of the present one.

In a review of a book of the character of the present text, one has only to discuss questions of pedagogy. The author desires to bring out a closer relation between rational numbers and quadratic numbers. This he accomplishes by complicating the elements of rational numbers with the unnecessary machinery of quadratic numbers! We find on page 91 Wilson's theorem stated in the form

$$r_1 r_2 \cdots r_k + 1 \equiv 0 \pmod{p}, \quad k = \phi(p),$$

where $r_1, \cdots, r_k$ form a complete set of residues modulo p, a prime. A similar unnecessary complication is met on page 105. Positive and negative primes p are used, so that one must face $\phi(p) = |p| - 1$.

On page 247 the "introduction of the ideal" should read introduction of ideals. After stating formally theorem A and devoting fifteen lines to its proof, the author informs us that the "theorem therefore fails." Similarly, on pages 250–251, theorems are formally stated and later shown "not to hold in general." This peculiar style of pedagogy is decidedly a novelty to the reviewer. It may at least serve to put the reader on his guard as to the fallibility of "what is written in the book." In the present instance the reader may be prepared for the actual error in the theory as presented on page 316, where the author makes a general theorem depend upon an equation which he has earlier proved only for a few special cases. His single reference is to the case of Gauss's field of complex

integers ϕ-ϕi. Several errors appear on page 275; in the line below (2) and that above (3), m must be replaced by m_1; while the use of $\mathfrak{p}_1, \mathfrak{p}_2$ for δ_1, δ_2 is merely an oversight. At the bottom of page 255 the author speaks of introducing ideals into a number field.

Many of the proofs employed by the author in his case of quadratic fields are mere substitutions of 2 for n in the standard proofs on algebraic fields of degree n. In one place he says: "This proof could have been somewhat simplified had greater use been made of the fact that the realm under consideration was quadratic, but it seemed desirable to give the proof in a form at once extendable to realms of any degree." The reference is to his three-page proof that every quadratic field has a basis! Now the real justification of a special treatment of the quadratic field lies in the fact that particularly simple proofs may be given and the reader made acquainted with an important example without the algebraic difficulties inherent in the general field. The above remarks will serve to show how the author has filled 300 pages with properties of quadratic number, without entering upon a discussion of the class number, characters, genera and other important topics on quadratic numbers.

In the matter of references the author has been particularly unfortunate. In a book barely entering upon the threshold of the theory, a scarcity of references would have been entirely justifiable. But to give hundreds of references to a certain report on the subject (excellent although it be) and to completely ignore the literature and not even mention the names of the discoverers of the theorems is against all scientific traditions.

L. E. DICKSON

THE RELATION OF COLLOIDAL SILICA TO CERTAIN IMPERMEABLE SOILS

THE interpretation of recent soil bacteriological studies upon the Truckee-Carson Irrigation Project at Fallon, Nev., is in many cases difficult because of the impermeability to irrigation water on certain shortly defined areas. These impermeable areas support practically no crop growth, although the soil is very similar to that of the good areas in appearance and soluble salt content. During the past two years it has been my belief, based upon rough estimations of the silica that could be washed out from samples of soil from good and poor spots upon the United States Experimental Farm at Fallon, Nev., that at least in some instances the permeability and impermeability bore some relation to the occurrence of silica in a colloidal condition. Certain peculiarities of the behavior of soil samples from good and poor spots toward colloidal silica have been noted in the laboratory. These facts are only indirectly connected with our soil bacteriological studies and seem of themselves of sufficient interest to warrant publication at this time.

The following is a brief summary of laboratory results which seem to confirm the theory that in certain soils impermeability is associated with the occurrence of colloidal silica.

One-gram samples of good soil shaken in ten cubic centimeters of carefully dialyzed colloidal silicic acid of specific gravity of 1.0108 coagulates in from three to eight hours at 28° C.

One-gram samples of bad soil similarly treated not only do not coagulate the silica but hold it in a colloidal condition even after the check tube of pure silicic acid has coagulated.

The mixing of small quantities of calcium chloride, calcium sulphate or dilute acids with samples of bad soil before their addition to the silicic acid enables them to coagulate the tube of colloidal silicic acid in as short a time as that necessary for samples of good soil.

The treatment of samples of bad soil with calcium chloride, calcium sulphate, or dilute acids destroys their impermeable character, in some cases enabling water to percolate through them as rapidly as in the case of good soils.

In these experiments it has been found that the two essentials are, first, a high degree of purity of the colloidal silicic acid; and,

second, the preparation of the colloidal silicic acid at such a concentration that in its pure condition it will remain uncoagulated for about ten days. If the preparation is much more dilute than this it may fail to coagulate even with the good soils, while if it is much more concentrated it coagulates, presumably from mechanical reasons, almost instantly upon adding soil samples from either good or poor spots.

Whether these results may have a practical bearing upon the management of the refractory soils in question can be determined only by rather extensive field experiments. It is believed, however, that the action of calcium sulphate (gypsum) will improve these soils in the field as it has in the laboratory and that the crop-producing power of the poor areas may then approach that of the good areas.

KARL F. KELLERMAN
BUREAU OF PLANT INDUSTRY,
WASHINGTON, D. C.

THE BOTANICAL SOCIETY OF AMERICA

THE annual meeting of the Botanical Society of America was held at the University of Minnesota, Minneapolis, Minn., December 27 to 30, 1910. The officers for 1911 are:

President—W. G. Farlow, Harvard University.

Vice-president—A. W. Evans, Yale University.

Treasurer—Arthur Hollick, New York Botanical Garden.

Secretary—Geo. T. Moore, Missouri Botanical Garden.

Councilors—F. E. Clements, University of Minnesota, C. L. Shear, Bureau Plant Industry; R. A. Harper, University of Wisconsin.

The following associate members were elected to full membership: O. W. Caldwell, University of Chicago; E. W. Olive, South Dakota College of Agriculture, R. H. Pond, Texas Agricultural Experiment Station, A. D. Selby, Ohio Experiment Station, M. B. Thomas, Wabash College; and the following botanists were elected to associate membership: Harley Harris Bartlett, Bureau of Plant Industry; Frederick K. Butters, University of Minnesota, H. L. Bolley, North Dakota Agricultural College; Merritt Lyndon Fernald, Gray Herbarium; Douglas Houghton Campbell, Stanford University; William Crocker, University of Chicago; Abel Joel Grout, Curtis High School, New York City, Hans Th. Guessow, Dominion Botanist, Ottawa, Canada; Frederick De Forest Heald, University of Texas; E. C. Johnson, U. S. Department of Agriculture, Frank D. Kern, Purdue University, C. H. Kauffman, University of Michigan, Ivey Foreman Lewis, Randolph-Macon College, Emile P. Mienecke, Bureau Plant Industry, Raymond J. Pool, University of Nebraska; Chas. V. Piper, U. S. Department of Agriculture, Leigh H. Pennington, Syracuse University, Carl Otto Rosendahl, University of Minnesota; Paul C. Standley, National Museum, Fred J. Seaver, New York Botanical Garden, Josephine E. Tilden, University of Minnesota, Chas. Edw. Amory Winslow, College of City of New York, Herbert Hice Whetzel, Cornell University; E. Mead Wilcox, University of Nebraska.

The symposium on "Some Aspects of Plant Pathology" was held at the Agricultural College on Thursday and participated in by Professor L. R. Jones, who spoke on "The Relation of Plant Pathology to Other Sciences", Professor B. M. Duggar, who spoke on "Physiological Plant Pathology," and Professor E. M. Freeman, who spoke on "Resistance and Immunity in Plant Diseases." These papers, with the discussions, will be published and reprints distributed to the members of the society.

At the close of the dinner for botanists, the conference on botanical teaching was held, in which Professor C. E. Bessey, O. W. Caldwell, F. E. Clements, J. M. Coulter, R. A. Harper and F. C. Newcombe participated. This discussion will likewise be published and distributed to the members.

Following are abstracts of the papers presented at the scientific sessions held on Wednesday and Friday afternoon.

Light as a Formative Factor in the Habit of Growth of Asparagus plumosus: FREDERICK C. NEWCOMBE, University of Michigan.

The shoots of this house plant grow erect for a time, and then turn their tips to the horizontal position. Although this horizontal bend is geotropic, as shown by the klinostat, the process of bending is profoundly influenced by the presence of light. The new shoots which start up from subterranean buds are indefinitely nourished in the dark by the older shoots left in the light.

If a new shoot, a day before the bend was to be made, were covered by an opaque inverted cone of paper, the horizontal bend would occur without noticeable change from the normal. If the light were excluded two days before the time for the

bending, the time of bending would be delayed. Still greater delay in bending would follow an earlier covering.

If, now, a subterranean bud which has started to unfold be covered and caused to grow without ever being in the light, the period of erect growth will be greatly prolonged, the horizontal bend will never be complete, but, instead, there will be nutations up and down through an arc of usually 20° to 50°, these nutations lasting indefinitely.

This behavior may fall under one of two hypotheses: (1) etiolation disarranges the normal processes; (2) there is a weak inheritance of diageotropism which needs the supporting influence of light induction to give the usual form to the plant.

The Relation of Transpiration to the Water-content of Leaves in the Ocotillo: FRANCIS E. LLOYD, Alabama Polytechnic Institute.

During the summer of 1910 at the Desert Botanical Laboratory comparative volumetric and gravimetric data were obtained for transpiration in the ocotillo (*Fouquieria splendens*) during a period of twenty-four hours. The moisture-content of the leaves of this plant was also determined for a similar period on two occasions. The behavior of the stomata was determined by the measurement of 300 for each of six hours during the twenty-four. The following conclusions are drawn.

Comparative volumetric and gravimetric data show that, in the ocotillo, the ratio between the intake and outgo of water is not a constant, but that, aside from changes of secondary nature, the outgo is greater during the day than the intake. The reverse relation obtains during the night.

The amount of water relative to the dry weight of the leaves decreases till some time in the earlier part of the afternoon. After this time it increases till about four A.M.

This change in water content of the leaf explains at least in part the discrepancy between the income and outgo of water.

The decrease of water in the leaf occurs during the period of opening of the stomata. These organs are therefore not closely regulatory of the rate of transpiration.

Relation of Certain Fungi to Nitrogen Fixation: B. M. DUGGAR and LEWIS KNUDSON, Cornell University.

As a result of comparatively recent investigations in Europe and America it has been reported that many fungi growing in solution cultures have a power of "fixing" atmospheric nitrogen.

It has seemed necessary to determine by more extensive experiments the amount of this fixation by fungi from diverse habitats grown under a variety of conditions. The following fungi were employed in two series of experiments involving about 400 flask cultures: *Coprinus comatus*, *Dædalia Quercina*, *Polyporus sulphureus*, *Trichoderma lignicola* and *Aspergillus niger*.

The culture media employed consisted of (1) a nutrient salt solution, such as used by other investigators, to which was added, in some cases, known amounts of combined nitrogen, and variable quantities of sugar, (2) filter paper moistened with preceding solutions; (3) quartz or graphite moistened with nutrient solutions, decoctions of mangel-wurzels, (5) dead leaves which were dried, powdered and moistened, (6) dried leaves, as in the preceding, with varying quantities of sugar; (7) decayed leaves or leaf mould, (8) leaf mould with varying quantities of sugar, and (9) leaf mould well aerated by including with it balls of filter paper. The nitrogen determinations indicate that there is no fixation of atmospheric nitrogen except possibly in certain cultures of *Aspergillus niger*. In many cases there is a nitrogen loss which is to be accounted for, usually, by the production of N_2.

In a third series of experiments additional fungi have been tested, and the experiments of other investigators duplicated. In the light of the results reported general indications were given respecting the possibility of nitrogen fixation by this group of organisms.

Cryptomeric Inheritance in Onagra: C. STUART GAGER, The Brooklyn Botanic Garden.

Reference was made to an abnormal plant of *Onagra biennis* that appeared in a pedigreed culture following exposure to radium rays of the ovule employed in producing the plant. The plant possessed two primary shoot-systems (rosettes and subsequent cauline stems) of equivalent value, but manifesting entirely unlike morphological characters. Photographs were shown, and various possibilities were suggested as to the cause or causes of the anomaly. That the effect was due to the exposure to radium rays was held to be possible, though not conclusively shown. The antecedent history of the plant, and the fact that hybrids between the two unlike halves manifested, in the F_1 and F_2 generations, the characters of only one of the parent shoots, was interpreted to emphasize the fact, already recognized, that the inheritance of a character and its expression are two quite different phenomena.

Sex Latency in the Gametophyte of Onoclea struthiopteris F C Newcombe University of Michigan

The experimental work of Miss Wuist on the sex of the gametophyte of *Onoclea struthiopteris* showed, as published last year in the *Botanical Gazette*, that the female gametophyte may be made to give rise to antheridia Miss Wuist's later work has shown that spores of the same species, which formed at first narrow ameristic plants bearing antheridia, subsequently developed heart shaped proliferations at their apices bearing archegonia To stimulate the outgrowth of the archegonia bearing proliferations, the antheridia bearing gametophytes were transferred from humus soil in pots to a Knop's solution, where they produced the meristic, heart-shaped, secondary gametophytes with their archegonia

Reversible Sex mutants in Lychnis dioica George Harrison Shull, Station for Experimental Evolution, Carnegie Institution

Hermaphrodite mutants were discovered in 1908 in cultures of *Lychnis dioica*, and the following year a report was made on the first generation cross of these with females and normal males The present paper presents data from more than one hundred families in which these hermaphrodites were used, most of these families representing the second generation from the original hermaphrodites It is shown that the hermaphrodite character is a modified male condition, not due to the presence of an independent modifying factor which was suggested by Correns, but obviously a modified condition of the male-producing gene itself The hermaphrodite character is not transmitted by the egg, but only by the sperm Among the offspring of these hermaphrodites have appeared a few normal males in such small proportions (a small fraction of one per cent) that they can only be considered male mutants, since they also breed true to their male character The appearance of hermaphrodite mutants in families produced from normal males and the appearance, in turn, of male mutants in families produced by hermaphrodites, suggest reversible modifications of a single gene rather than the addition of a gene to those previously present, and a subtraction of a gene from them These results may thus have an important bearing upon the "presence and absence" hypothesis.

An Isolated Prairie Grove and its Ecological Significance: Henry Allan Gleason, University of Michigan

Bur Oak Grove is located in Champaign County, Ill , and is about one by three miles in size. It is peculiar in being located at some distance from a stream and surrounded on all sides by prairie, while most of the forest tracts in central Illinois are along the larger water courses The prevailing trees in the grove are *Quercus velutina, Q. imbricaria, Q. macrocarpa, Carya ovata, C. cordiformis* and *Juglans nigra*, with scattered individuals of other species The variation in the composition of the forest indicates that it migrated into the region from the southeast. The grove is not continuous, but is broken by areas of low ground which contain permanent standing water On the moraine north of the grove are found some plants which are regarded as forest relics, now growing in the prairie It is concluded that the whole moraine was formerly covered with forest, which extended also some distance out on either side Since the introduction of prairie fires this forest has been destroyed, except Bur Oak Grove, which is protected by the standing water against attacks of fire The more general conclusion drawn is that forests were formerly of much wider extent in Illinois than at present, but it is distinctly stated that the prairies do not owe their origin to prairie fires

Evaporation in its Relation to the Prairie Problem B Shimek, Iowa State University.

The fact that surfaces exposed to the south and southwest in the Mississippi Valley are treeless has been frequently noted Where changes in topography are abrupt the transition from forest to prairie is likewise abrupt The prairie plants are essentially xerophytic, the forest plants mesophytic The former are found upon the surfaces exposed to sun and summer winds, the latter in sheltered places. Field observations on rate of evaporation on treeless and forested areas, made in western and northwestern Iowa, show that it is much greater on prairie surfaces than in the adjacent forest, and materially greater than on contiguous areas which had been covered with forest but are now cleared. This is true even in the vicinity of larger bodies of water. The results of these observations are presented in tabulated form, and are represented by curves. They show that evaporation increases with temperature and velocity of the wind, and that when the temperature is high the fluctuations in evaporation are caused by changes in wind velocity. The bearing of these results upon the prairie problem is discussed.

Structure of Adult Cycad Trunks: Charles J. Chamberlain, University of Chicago.

While the structure of the cycad seedling is

fairly well known, comparatively little attention has been given to the structure of the adult plant, doubtless on account of the difficulty of securing material.

In an adult stem of *Zamia floridana* 5.5 cm. in diameter the zone of vascular tissue was 2.5 mm. in width. In a plant of *Ceratozamia mexicana* with a stem 14 cm. in diameter the zone measured 5 mm. in width. In *Dioon edule* a stem 21 cm. in diameter showed a vascular zone 9 mm. wide. Compared with these narrow zones, the vascular zone in *Dioon spinulosum* is surprisingly wide, reaching a width of 7.5 cm. in a trunk 32 cm. in diameter.

In *Dioon spinulosum* there are definite growth rings but they are not annual, for not more than one ring is formed in a dozen years, or perhaps in twenty. Medullary rays are as prominent as in a dicotyl. *Dioon edule* also shows growth rings but they are not so prominent as in *D. spinulosum*. No growth rings were found in the specimen of *Ceratozamia*.

In none of these specimens were there any zones of wood in the cortex. It is possible that the periodicity which in *Cycas* produces a zone of wood in the cortex, produces in *Dioon* a growth ring resembling the annual ring.

Spruce Burls: HERMANN VON SCHRENK, Missouri Botanical Garden.

The author describes some burls observed in certain parts of Maine and Minnesota on the white spruce. They occur on all parts of an affected tree, either singly or in large numbers on one tree. The external appearance of the burl is described and their internal structure. Attention is called to the formation of diamond shaped holes, which are probably the result of unequal strains.

The Origin of the Blepharoplast in Polytrichum: C. E. ALLEN, University of Wisconsin.

A dark-staining granule, the center of a system of radiations, appears in the cytoplasm of each cell of the penultimate antheridial generation. In previous cell generations there were kinoplasmic bodies of varying forms whose behavior was definitely related to spindle formation; but no structure that seems genetically related to the centrosome-like body that participates in the final division.

This central body divides; the two daughter granules, each surrounded by an aster, diverge until they lie at opposite sides of the nucleus, and a rudimentary spindle appears between them. The central bodies are conspicuous until about the time of the disappearance of the nuclear membrane; from this time on, they stain less deeply, some of the polar radiations disappear; and, although a granule can usually be recognized at either spindle pole which is probably the central body already described, its identity is often uncertain, and sometimes no such granule is visible.

After cell division is completed, a conspicuous body is again visible in each daughter cell, usually appearing to lie in the neighborhood of the former spindle pole; this body functions as a blepharoplast. There seems no reasonable doubt that the blepharoplast is identical with the previously present central body, which persisted during the division of the mother cell, although the lessened affinity of the central body for stains made it less conspicuous at certain stages.

The Method of Chromosome Reduction. R. R. GATES, Missouri Botanical Garden.

I have previously suggested that in some plants reduction takes place by telosynapsis, and in others probably by parasynapsis. Comparative studies have confirmed this view, but the difference between telosynapsis and parasynapsis is not believed to be of hereditary or phylogenetic significance. Rather is it merely a matter of cell mechanics, long, thread-like chromosomes usually pairing side by side and short ones end to end. The only essential and universal feature of meiosis is the segregation of the members of homologous pairs of whole somatic chromosomes. The function of synapsis is not to bring about a pairing of these homologous chromosomes, because they are paired throughout the sporophyte or soma. Neither is it to effect an interchange of chromomeres or other particles, since the chromosome is considered the unit of morphological nuclear structure; or even of "influences," since this could take place equally well or better in any "resting" nucleus. Synapsis is, therefore, not the final delayed act of fertilization, and is not of fundamental significance in the life cycle. It is, partly at least, explained by the change in the karyoplasmic relation which takes place during synapsis, owing to the fact that a segregation of chromosomes is intercalated between two ordinary mitoses.

On the Organization and Reconstruction of the Nuclei in the Root-tips of Podophyllum peltatum. JAMES BERTRAM OVERTON, University of Wisconsin.

Although a number of valuable papers, dealing with vegetative nuclear divisions, have recently appeared, notably those of Van Wisselingh

Grégoire and his students, Haecker, Strasburger, Bonnevie, Němec and Lundegård, a detailed account of the behavior of the chromosomes during rest has until recently been largely neglected. I have endeavored to follow in detail the various changes which the chromosomes of the telephase undergo during their passage into the resting nucleus, to follow their structural changes and arrangement in the resting nuclei, and also to determine how the visible chromosomes are reformed preparatory to division. During the passage of the chromosomes from the equatorial plate to the poles, they exhibit a progressive alveolation and vacuolation. Transparent spots appear in each chromosome. Each chromosome is composed of chromatic granules, closely massed in a linin substratum. By means of the progressive alveolation and vacuolation these chromatic granules are eventually separated. This process continues until conspicuous anastomosing vacuoles appear on the inside, increasing the size of the chromosome. These enlarged chromosomes often touch each other laterally, but never anastomose, as has been described by some authors. Each chromosome ultimately forms an independent reticulum. The reticulum of the resting nucleus thus consists of a number of these smaller elementary reticula. Conversely, during the earlier prophases of division, the chromosomes become more condensed and distinct and, joining end to end, give rise to the spirem, which is at first broad and reticulate, but eventually becomes densely chromatic. The mature spirem is not continuously chromatic, but consists of the individual condensed chromosomes united serially by visible linin intervals. In the writer's opinion the results strongly support the view of the individuality of the chromosomes.

The Nuclear Conditions in Certain Short-cycled Rusts: EDGAR W. OLIVE, South Dakota State College.

Two general types of short-cycled lepto- and micro-rusts have been recognized with reference to the time of inauguration of the binucleate condition. In one type, the binucleate condition arises at the base of the young teleutospore sori. This type is illustrated by *Puccinia elegans*, *P. asteris* and *P. malvacearum*. In the other type, the binucleate condition arises at some indefinite point earlier in the life history, in the vegetative mycelium. Illustrations of this type are apparently more numerous.

Except the one species, *Puccinia elegans*, in which sexual cell fusions have already been worked out, the method of initiation of the binucleated condition is still problematical.

In two forms, evidences of occasional multinucleated cells were found in the young sori.

Uromyces Rudbeckiæ was found to present an enigmatical variation, in that all the cells, teleutospores as well as vegetative mycelium, were discovered to possess each but one nucleus. No explanation can be offered at present for this unique phenomenon.

Teratological Forms of Oxycoccus macrocarpus: C. L. SHEAR, U. S. Department of Agriculture.

A malformation of the cranberry plant, of both economic and scientific interest, occurs about Grand Rapids, Wis. Metamorphy of the floral organs is the most important and striking characteristic of the trouble. The flowers become erect instead of drooping, the calyx and corolla, and frequently the stamens and pistil, are changed into leaf-like structures. In the most aggravated cases the floral axis is elongated and the floral organs are represented by whorls of small leaves, or the flower may be replaced by a slender shoot bearing small alternate leaves. No insects or fungi have been found to bear a causal relation to the malformation. It is believed to be due, primarily, to prolonged and excessive stimulation of vegetative growth.

Rust of Tsuga canadensis: PERLEY SPAULDING, U. S. Department of Agriculture.

Collections of the rusts occurring on *Tsuga* have been made for several years. Most of them have proved to be *Peridermium Peckii*. This ranges from Wisconsin to northern New York and Vermont, southward to North Carolina. It has been collected on the new host *Tsuga caroliniana* in North Carolina by Dr. A. H. Graves. The collections not belonging to *Peridermium Peckii* were separated into two forms: one on the young shoots, and the other on the green cones, in both cases on *T. canadensis*. The latter form is named *Cæoma tsugæ* sp. nov. The former presents no apparent specific difference from the latter, and it is for the present considered identical with it. Fresh material is necessary to determine this point with certainty, however.

A Plea for Organized Research in the Tropics: PEHR OLSSON-SEFFER. (Introduced by Wm. Trelease.)

A general discussion of the history of scientific research as carried on by various nations, with a special consideration of the conditions in tropical America and the numerous possibilities for work in all lines of botany.

American Botanical Societies and Meetings W. F. GANONG, Smith College.

Report upon the results of an inquiry among a number of botanists regarding the present relations of the various botanical societies and the methods of conducting the meetings

GEORGE T MOORE,
Secretary

THE SECOND ANNUAL MEETING OF THE AMERICAN SOCIETY FOR PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS [1]

THIS society had a very successful meeting at the Yale Medical School and the Sheffield Scientific School, the Physiological and Biochemical Societies met at the same time

The following program was presented, unusual i terest was taken in the discussions

W Salant, "The Pharmacology of Oil of Chenopodium"

A S Loevenhart, "Further Observations on the Action of Iodoso- and Iodoxybenzoic Acids"

C W Edmunds and W W Hale, "Physiological Standardization of Ergot"

L G Rowntree (with J T Geraghty), "Additional Data relating to the use of Phenolsulphonephthalein as a Functional Test for the Kidney"

H. C Wood, Jr, "The Vaso-motor System of the Pulmonary Circulation"

C. J Wiggers, "The Modifying Influence of Anemia on the Actions of some Well known Drugs."

L G Rowntree and J. J Abel, "Further Experiments in the Field of Specific Chemo-therapeutics."

T S Githens and S J Meltzer, "The Control of Strychnine Poisoning by Means of Insufflation and Ether"

C. W Green, "The Action of Strophanthin on the Isolated Mammalian Heart"

G Carr (by invitation), "The Action of Acetanilid on Cardiac Muscle"

W. Salant (with J B Rieger), "The Elimination of Creatin and Creatinin after the Administration of Caffeine."

W Salant (with I K Phelps), "The Influence of Caffeine on Protein Metabolism"

C. Voegtlin (with B. M Bernheim), "The Rôle of the Portal Circulation of the Liver in Bile Formation and Jaundice."

H G Barbour (by invitation) and J. J. Abel, "Tetanic Convulsions in Frogs produced by Acid Fuchsin and their Relation to the Problem of Inhibition in the Central Nervous System"

J Auer and S J Meltzer, "On Intramuscular Absorption"

D R Joseph and S J Meltzer, "The Action of Sodium Chloride upon the Phenomena following the Removal of the Parathyroids in Dogs"

W J Gies, "Experiments with Salts of Aluminium and Beryllium"

The following new members were elected S P Beebe, Cornell University Medical College, New York, R B Gibson, University of Missouri, P H Hiss, Jr, Columbia University, Paul Lewis, University of Pennsylvania, L B Mendel, Yale University, Isaac Ott, Medico Chirurgical College, Philadelphia, J H Pratt, Harvard University

The following officers were elected for the year 1911

President—J J Abel

Secretary—Reid Hunt

Treasurer—A S Loevenhart

Additional Members of Council—W deB Mac Nider, G B Wallace

Membership Committee—S J Meltzer, C W Edmunds, Torald Sollmann

The following resolutions were adopted concerning the recent death of Dr C A Herter, one of the charter members of the society

"By the death of Dr. Christian A. Herter, one of its charter members and founders, the American Society of Pharmacology and Experimental Therapeutics has suffered a loss which it can but inadequately express Dr Herter's breadth of view, his intimate knowledge and grasp of vital experimental problems, his clearness of expression and his valuable contributions to medical science made his connection with the society of great value to it His encouragement and ever ready assistance in the work of younger men, his appreciation of their difficulties, his own constancy in adhering to the high ideals of earnest and sincere work which he taught to them have made his death a personal loss to each individual member

"The sorrow felt by the members of the society, however deep it may be, is but a small part of the general sorrow felt by the large number of men throughout this country with whom Dr Herter came directly or indirectly in contact The society desires to express its share of this sorrow, however, and it is therefore

"*Resolved*, that there be spread upon the record of its minutes this expression of its feeling of loss at the death of Dr. Herter, of its sincere

[1] New Haven, Conn., December 28–30, 1910

appreciation of his work and of its deep admiration of his personal character

Committee { Reid Hunt
George B Wallace
A N Richards"

Hygienic Laboratory,

Reid Hunt,
Secretary

SOCIETIES AND ACADEMIES

THE BIOLOGICAL SOCIETY OF WASHINGTON

The 477th regular meeting of the society was held January 6, 1911, with President David White in the chair and fifty one persons present

Two new members were elected and standing committees announced by the president

Barton W Evermann reported observations on the fly catching habits of the common brown rat

C D Marsh called attention to a report by Sars on crustacea from Lake Tanganyika, and stated that the list, so far as copepods are concerned, fails to bear out the theory that this lake is of very ancient origin

The following communications were presented

Notes on the Aspens I Tidestrom

The speaker gave the history and relationship of several American and European forms of the genus *Populus* He showed that the western quaking aspen differs in several particulars from the eastern, and proposed a new name for the western form A number of herbarium specimens illustrated the remarks

Some Nesting Habits of Water Ousels and Cuckoos Ned Dearborn

The remarks were illustrated by photographs of the birds and nests The observations on the water ousel were made in Spearfish Canyon, S D, and in Santa Fe Canyon, N M, during last summer, those on the black-billed and yellow-billed cuckoos were made at Joliet, Ill, in 1906

A Recently Imported Enemy of Alfalfa F M Webster

The alfalfa or lucern weevil (*Phytonomus murinus*) was introduced into this country, probably in the packing or in packages of articles of international commerce, some time prior to 1904, when it was first discovered by the entomologists of the Utah Agricultural Experiment Station attacking a small field of alfalfa in the vicinity of Salt Lake City, Utah From this point it has since that time spread over the country northward to near Ogden and southward to beyond Provo and from a considerable distance westward of Tooele, very nearly to the borders of Wyoming

The eggs are deposited chiefly in punctures made in the young stems by the adult beetles, the larvæ, as soon as they hatch, make their way to the tender growing crowns of the plants, feeding upon the unfolding leaves and tender stems, and thus prevent growth of the young plants. Later on in the season, after the insects have reached the adult stage, these still attack the alfalfa plants by gnawing the bark from the stem, thus destroying them

In many alfalfa fields about Salt Lake, at the time for mowing the first crop of hay, the plants had not made sufficient growth to admit of mowing, while the second crop was seriously damaged by the feeding of the adult beetles as just described Approximately, damage to the amount of a half million dollars was caused during the last year by this pest in Utah

No thoroughly practical measures have been found for preventing the spread of the pest or very materially reducing the results of its depredations

The habit of the adults in hiding away in baled hay, in fruit packages, or almost any other similar articles of commerce, as well as their attaching themselves to freight cars and hiding themselves in the vestibules of Pullman sleeping cars, makes their diffusion by railways almost unpreventable Twenty seven individuals were taken from the vestibule of one sleeping car attached to a train at Salt Lake City last July Also, the adult insects fly about freely during the summer and being carried by the winds are also in this manner widely diffused

The present indications are that the insect will make its appearance in southern Idaho, southern Wyoming and eastern Nevada the coming spring Fortunately, alfalfa does not enter into international commerce as does cotton, therefore this insect is not likely to affect articles of international commerce. But over the western country, where it seems likely to diffuse itself and carry on its destructive work, there is much territory where alfalfa is the only crop that can be raised, and if this is destroyed the farmers will be placed in sore straits and confronted with a more serious problem than is brought about by any other insect known to occur in this country Over a good portion of the country west of the one hundredth meridian alfalfa is the money crop of the farmers, and any influence tending to prevent or interfere with the cultivation of this, will constitute a calamity throughout that country

The insect has no natural enemies excepting frogs and toads Birds do not appear to relish them. No insect enemies are known, or have yet been discovered, and fungus diseases that attack similar larvæ in the east have failed to become established when introduced from the eastern part of the country.

Secretary

THE HELMINTHOLOGICAL SOCIETY OF WASHINGTON

THE first meeting of the society was held in the rooms of the zoological division of the Public Health and Marine Hospital Service on October 8, 1910, Dr Stiles acting as host, Dr Garrison as chairman Mr Hall was elected secretary for the year

Dr Pfender noted the publication of a recent article recording the finding of *Necator americanus* in New Guinea for the first time

Dr Garrison exhibited specimens of *Davainea madagascariensis* from man and read a paper, to be published in the *Philippine Journal of Science*, dealing with the case and describing the specimens The material, consisting of one complete and four incomplete and headless specimens, was collected from an adult male native in the Philippines It is the first case from this locality and the tenth recorded case This case indicates a more or less general distribution of the parasite throughout the tropics Cases occur in children and adults and the lack of records from any host save man since the parasite was first found in 1867 indicates that man is the normal host So far the parasite has been recorded only from coast regions, but this may be due to inadequate investigation in the interior Dr Garrison's description of the anatomy was illustrated by photographs

Dr Stiles gave a talk on the International Zoological Congress at Gratz He discussed the newly elected international committee on medical zoology and noted the following plans which the committee had taken up the agreement on national repositories for collections dealing with medical zoology and for the deposition of type material; a working agreement between this committee and the Commission on Zoological Nomenclature to determine and fix upon the correct names of the parasites of man and later of those of domesticated and the more important wild animals; the securing of material from the various groups for the use of specialists; the location of existing collections and especially type specimens; the securing of better recognition of zoology in medical schools where work in tropical medicine is done, and the issuing of a model syllabus for such a zoological course, the collection of methods of technique, and the selection of corresponding members with a view to promoting harmony and cooperation and avoiding dissension and unwarranted criticism in zoological circles

THE second regular meeting of the society was held in the rooms of the zoological division of the Hygienic Laboratory, December 1, 1910, Dr Stiles acting as host, Dr Ransom as chairman.

Dr Stiles presented an abstract of an unpublished paper on rural sanitation, with special reference to the disposal of fæces A proper disposal of fæces is the greatest single factor in combating zoo parasitic diseases Where the installation of a sewer system is not feasible, the dry disposal method has been considered the best In this the fæces are covered with dirt or lime The system depends on the cooperation of all of the members of the community for its success, and this fact constitutes one of the greatest objections to it Children and the majority of the southern negroes can not be depended on to cooperate The unsatisfactory character of this system being evident, efforts have been made to devise a satisfactory wet system Many tests had given unsatisfactory results, but the wet system devised and described by Lumsden, Roberts and Stiles seems to have overcome the final objections. The paper dealt also with the objections to the dry system as they had been worked out at Wilmington, N C Some of the findings were as follows (1) The sand under and around dry system privies is not safe five months after the last use of the privy Sand which had been dried out twice showed two encysted larvæ on the one hundred and fifty-first day. Life was not demonstrated by movement, but the specimens were histologically perfect and could not have been dead more than a day or two if they were dead (2) After four months the infection may be greatly reduced and in some cases perhaps entirely eliminated (3) After five months in sand, and after drying out twice, live *Ascaris* eggs may be found after all the hookworm eggs and embryos have perished. *Ascaris* eggs were found apparently alive after 156 days. (4) Hookworm eggs were identifiable after 151 days (5) When fæcal material is subjected to water decomposition for 70 days, most of the hookworm eggs die, but some are still alive. (6) No hookworm eggs were found alive after about four to five months in fæces and water. (7) It is probable

that hookworm eggs perish in three months in fæcal material in water. If this is proved, then the effluent from the L R S barrel privy should be stored three months before using as fertilizer. The use of fæces as fertilizer is receiving especial attention for the reason that the commercial argument carries more weight with some people than does the idea of protection to human life and health. (8) In fæces decomposing in water, 80 per cent. of the *Ascaris* eggs are dead in four or five months, but some are still alive, thus outlasting the hookworm. (9) Chloride of lime in the proportion of a quarter pound to about ten quarts of water does not kill hookworm eggs in 22 to 40 hours. After four days the eggs are still microscopically normal.

Flies feed and breed in the dry system. In one place about 80 privies were examined. Although lime was furnished free, it was only used generously in three cases, and flies were breeding in these places as in the others. The fæces are collected in wagons and buried; burial under a foot of soil being recommended. The carts carry and distribute flies. Experiments showed that flies developed and crawled up to the surface from fly-blown fæces buried under six and a half inches of sand, they came through 17 inches in 24 hours; and flies issued after burial under 48 inches of sand. Flies were obtained even after burial under six feet of sand. In the last two cases, the sand used was not sterilized but was pure sand carefully selected. These are final arguments against the dry system.

The system favors the sporulation of amœbæ. Flies can bring to the surface and distribute amœbæ spores or typhoid bacilli. Under some circumstances privies may be more important than the manure piles as breeding places for flies.

Dr. Stiles presented a note on spurious parasitism. Small oligochætes were sent in from three different states in three cases recently, with the claim that they were passed in the urine. These are assumed provisionally to be cases of contamination. In one case, however, it was claimed that they were passed in the presence of a physician and into a clean receptacle. A specimen of a small snake, identified by Dr. Stejneger as *Storeria dekayi*, was exhibited. This specimen was sent in from Pennsylvania with the claim that it had been passed from the bowels.

Dr. Cobb presented a note on the abundance of free-living nematodes in the soil. The number per acre amounts to thousands of millions. Reckoning the average length at one and one half millimeters, a modest estimate, the nematodes in one acre would extend from Washington to Chicago if placed end to end. One genus feeds almost exclusively on diatoms.

Dr. Garrison brought up the question as to the desirability of designating certain tropical stations as repositories for zoological material connected with the study of tropical medicine. Dr. Stiles stated that the international commission hoped to take up that subject in the not too distant future.

Dr. Ransom gave a brief summary of a paper entitled "The Nematodes Parasitic in the Alimentary Tract of Cattle, Sheep and other Ruminants," to be published as a bulletin of the Bureau of Animal Industry. The paper describes 50 species, at least 30 of which occur in the United States, the species described representing 18 genera belonging in the five families Ascaridæ, Strongylidæ, Filariidæ, Angiostomidæ and Trichinellidæ. The Strongylidæ are divided into the subfamilies Strongylinæ and Metastrongylinæ, and the Trichinellidæ are divided into two new subfamilies. Railliet's rejection of the subfamily Strongylinæ, following the application of the generic name *Strongylus* to the so called sclerostomes, and his substitution of the name Ankylostominæ was noted. A *Strongyloides* from the prong-horn antelope was noted as of particular interest. Members of the Angiostomidæ, to which this genus belongs, are characterized by a life cycle including two generations, one of free-living males and females, and another of parasitic hermaphroditic or parthenogenetic forms. In the species in question the parasitic adult molts repeatedly, and the eggs as passed lodge under the old cuticle and are carried away in the old skin when it is shed. It was noted that *Strongyloides longus* of the sheep is certainly identical with Wedl's *Trichosoma papillosum*. Two new species of *Capillaria* are described in the paper.

Mr. Hall gave a summary of a paper entitled "A Comparative Study of Methods of Examining Fæces for Evidences of Parasitism," to be published as a bulletin of the Bureau of Animal Industry. The paper gave the various methods used in examining fæces and indicated the application and limitation of each method on the basis of comparative studies. A new modification of technique which had been found more efficient than other methods was then demonstrated in the laboratory.

THE RELATIONS OF ISOSTASY TO GEODESY, GEOPHYSICS AND GEOLOGY[1]

WITHIN the past ten years geodetic observations have furnished positive proof that a close approximation to the condition called isostasy exists in the earth and comparatively near its surface.

Let the depth within which isostasy is found be called the depth of compensation. Think of a prismatic column which has for its base a unit area of the horizontal surface which lies at the depth of compensation, which has for its edges vertical lines, and has for its upper limit the actual irregular surface of the earth (or the sea surface if the upper end of the column is in the ocean) The condition called isostasy is defined by saying that the masses in all such columns are equal.

Fig 1 (p. 202) represents two such columns Column A is under the land and column B is adjacent to it under the ocean. If the condition called isostasy exists in two such columns having equal bases they have equal masses Note that if this is true the average density in column A must be less than the average density in column B, for the volume of column A is greater than that of column B. This may be partially expressed by the statement that each excess of mass represented by material lying above sea level is compensated for by a

[1] Address of retiring vice-president of Section D (Mechanical Science and Engineering) of the American Association for the Advancement of Science, at Minneapolis, December 29, 1910, by John F Hayford, director, College of Engineering, Northwestern University, Evanston, Ill

defect of density and, therefore, of mass in the material in the same vertical line below sea level and above the depth of compensation

Note that isostasy is defined in terms of masses and densities without regard to the manner in which this arrangement of masses and densities has been produced.

Isostasy is a condition of approximate equilibrium, not perfect equilibrium The total weight of column A being the same as that of column B, the pressure at the depth of compensation due to weight is the same under the two columns, and at this level there is equilibrium Above any selected higher level in the two columns such as that marked depth X in the figure, the mass is greater in column A than in column B[2] Therefore, at depth X the pressure due to weight is greater in A than in B, equilibrium does not exist, and the material in A at this level tends to move downward and to the right into B

The geodetic observations which have furnished a positive proof that a close approximation to the condition called isostasy exists in the earth are, first, 765 series of astronomic observations scattered over the United States from the Atlantic to the Pacific and from Canada to Mexico, and all connected by continuous triangulation,[3] and, second, determinations of the intensity of gravity at 89 stations scattered over the whole of the United States.[4]

The geodetic observations show that the most probable depth of compensation is 76 miles and that it is practically certain that it is not less than 62 nor more than 87 miles.[5]

Let the isostatic compensation be considered complete if in every column, such as those shown in Fig 1, the mass above the depth of compensation is the same as in every other column If the mass is greater or less than this in any one column, let us characterize the isostatic compensation as incomplete and measure the degree of incompleteness in terms of the excess or defect of mass

The geodetic observations show that the isostatic compensation under the United States is nearly complete It is not merely a compensation of the continent as a whole, it is a compensation of the separate, large, topographic features of the continent

[2] The density in column A, in which a defect of density exists to compensate for the excess of mass at the surface, being less than in column B, in which the reverse condition exists, the mass in column A below depth X is necessarily less than in column B below that level Hence the total masses in the two columns being equal, the mass in column A above depth X must be greater than in column B, as stated

[3] The evidence from these observations is given in full in "The Figure of the Earth and Isostasy from Measurements in the United States" and "Supplementary Investigation in 1909 of the Figure of the Earth and Isostasy," both by John F Hayford and both published by the Coast and Geodetic Survey.

[4] These have furnished evidence which corroborates that from the astronomical observations and triangulation This evidence has not been published except in brief and incomplete form (report of the sixteenth general conference of the International Geodetic Association, Vol 1, pp. 365–389, "The Effect of Topography and Isostatic Compensation upon the Intensity of Gravity," by John F Hayford), but it will probably be published in full within a year in a paper which is being prepared by Mr William Bowie, inspector of geodesy, Coast and Geodetic Survey, and the speaker It is expected that this will be published by the Coast and Geodetic Survey under the same title as the report presented at the International Geodetic Association to which reference has just been made

[5] This is the depth of the compensation if uniformly distributed with respect to depth, which seems to be the most probable assumption If the compensation is distributed in some other manner with respect to depth, the limiting depth of compensation is different, see pp 77–78 of the "Supplementary Investigation in 1909 of the Figure of the Earth and Isostasy"

There is an excess of mass in some columns and a defect in others, but the evidence indicates that the average excess in the areas of undercompensation is properly represented by a stratum only 250 feet thick having the same density as the surface portion of the earth (2.67). Similarly, the average defect of mass in the areas of overcompensation corresponds to a stratum only 250 feet thick.

Contrast these small excesses and defects of 250 feet with the actual elevations in the United States, 2,500 feet on an average for the whole country. If there were no isostatic compensation these actual elevations would represent excesses of mass. The compensation may properly be characterized as departing from completeness only one tenth on an average.

These are the facts, established by abundant geodetic evidence. These facts may not be removed or altered by showing that difficulties are encountered when one attempts to make them fit existing theories geological or otherwise. The theories must be tested by the facts and modified if necessary.

A close approach to the condition called isostasy certainly exists. It is uncertain how this condition has been produced; upon that point the geodetic observations furnish no direct evidence.

The recognition of isostasy in a definite and reasonable manner in the computations of the figure and size of the earth from astronomical observations and triangulation has nearly doubled the accuracy of the computed results. This recognition, combined with other improvements in methods of computation, has enabled the Coast and Geodetic Survey to compute the equatorial radius and the flattening of the earth from observations in the United States alone with greater accuracy than it was formerly possible to compute it from all the observations of the world combined—by such computations, for example, as those made by Bessel and Clark.

The evidence is clear that the present isostatic compensation is not an initial condition which has persisted since early geologic times. There is abundant geological evidence[6] that within the interval covered by the geologic record many thousands of feet of thickness of material have been eroded from some parts of the United States and adjacent regions and deposited in other parts, that changes of elevation of the surface amounting to thousands of feet have been produced in this and other ways, and that these changes have continued to take place in recent time. Hence it is evident that if there had been complete isostatic compensation in early geologic time, and no readjustment toward the isostatic condition had taken place since, the departure from complete compensation would now be measured by strata thousands of feet thick upon an average. In fact, the present departures from complete compensation are measured by strata only a few hundred feet thick—250 feet on an average. It is certain that a readjustment toward isostasy has been in progress during the period covered by geologic record.

Let us consider the tendency of gravitation to produce readjustment toward isostasy. Recur to the case indicated in Fig. 1. Columns *A* and *B* have been assumed to contain equal masses. There is complete isostatic compensation. The pressures at the bases of the two columns

[6] The paper entitled "Paleogeography of North America," by Charles Schuchert, pp. 427–606 of volume 20 of the *Bulletin of the Geological Society of America* may be cited as an example of such evidence marshaled in systematic form. Consult the fifty maps at the close of this publication for a graphic indication of the changes which have probably taken place on this continent.

are equal, and at any less depth, X, the pressure is greater in A than in B Now assume that in the normal course of events a large amount of material is being eroded from the high surface of column A and deposited on the low surface of column B After this erosion has been in progress for some time the isostatic compensation will no longer be perfect. The pressure at the base of B will be greater than at the base of A The pressure very near the top of B will still be less than at the same level in A so long as the top of A remains higher than the top of B. There will be some intermediate level at which the pressure in the two columns is the same. Call this level of temporary equality of pressure in the two columns the neutral level As the process of erosion and deposition progresses the neutral level will gradually progress upward from its original position at the base of the columns Eventually if no interchange of mass took place between the columns except at the surface, and no vertical displacement occurred in either column, the neutral level would reach the surface when the process of erosion and deposition became complete and the upper surfaces of the two columns were at the same level. During the process of erosion and deposition the excess of pressure in A at any level above the neutral level will continually decrease Similarly, at any level below the neutral level the excess of pressure in B will continually increase as the erosion progresses and the neutral level will rise Thus there will be established a continually increasing tendency for the material below the neutral level in B to be squeezed over into A. If the stresses tending to produce this undertow from the lower part of B to A become greater than the material can stand, the flow will take place as indicated by the arrow in the figure If the material flows without change of volume, as if it were incompressible, the upper part of A and its surface will be raised, the upper part of B and its surface will be lowered, the neutral level will sink and an approximation to the original conditions with complete isostatic compensation will be reestablished.

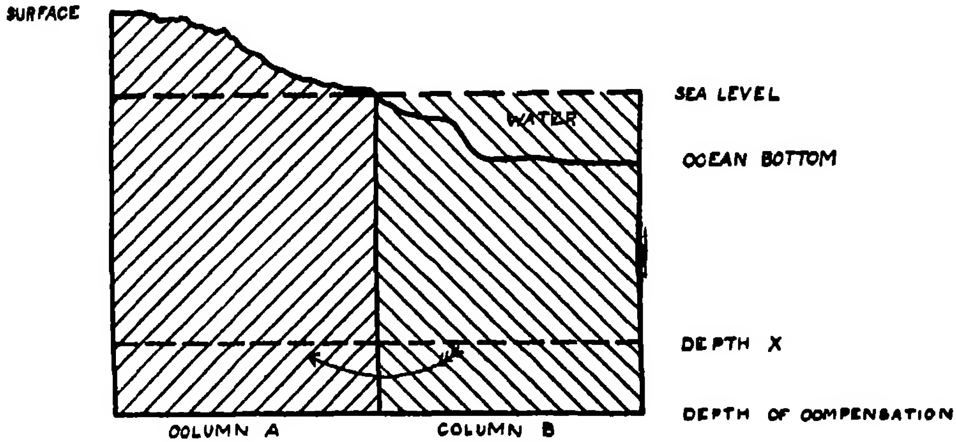

Fig. 1

This is the general case of isostatic readjustment by the action of gravitation alone. Gravitation tends to produce a deep undertow from the regions where deposition is taking place to the regions

where erosion is in progress, in the direction opposite to that of the surface transfer of material

Let us suppose that the isostatic compensation at a given stage in the earth's history is practically complete for a continent, that the process of erosion from the greater part of the continent and deposition around its margins is in progress, and that the process of readjustment by a deep undertow is in progress These processes will cause changes of pressure and temperature within the earth at certain places. It is important to study the probable effect of these changes upon the condition and especially upon the density of the material involved

At this point, in order to keep our subject in proper perspective, it is desirable to recall that the average defect in density under a continent corresponding to complete isostatic compensation is one per cent or less, the average excess of density under an ocean only about two per cent. and the maximum defect or excess under the highest parts of the continents or under the deepest parts of the ocean are but little greater than three per cent These are very small differences in density Differences larger than these are frequently observed between samples supposed to be alike.

If a layer of material 1,000 feet thick is eroded from one part of the earth's surface and deposited on another part the pressures must become appreciably reduced for a considerable distance below the eroded region and increased below the region of deposition. The heterogeneous material composing the earth is continually undergoing chemical changes. The expression chemical change is here used in its widest sense, the sense in which it includes the processes of solution, crystallization and changes of state between the solid, liquid and gaseous forms, includes the solution of gas in liquids, the solution of rock ingredients in water and their redeposition as new materials different from the original materials, and changes from an amorphous to a crystalline state, and vice versa All these and more are concerned in the complicated processes of metamorphism In the heterogeneous mixture at any point in the earth a great many changes are impending A relief of pressure at any given point tends to favor such changes as are accompanied by increase of volume and reduction of density, and an increase of pressure tends to have the reverse effect Many of these suggested chemical changes are accompanied by a change of much more than three per cent in density Changes of this nature in a small part of the material in any cubic mile may alter the average density as much as three per cent

A large reduction of pressure may reasonably be expected, by favoring certain chemical changes within the earth and opposing others, to bring about gradually with the lapse of ages a decrease of two or three per cent in the density of the material relieved of pressure

Under a region where erosion is in progress or has recently been in progress one should expect, therefore, that the chemical changes guided by reduced pressure will gradually produce increase in volume and a raising the surface, and conversely, under a region of deposition the chemical changes guided by increased pressure will gradually produce increase of density, reduction of volume and a lowering of the surface The surface changes will then favor more erosion and more deposition in the same regions as before. During this process the stresses due to gravitation, tending to produce an undertow and thereby an isostatic re-

adjustment, gradually increase until an undertow takes place and the isostatic condition is restored or nearly restored In this last state the surface of the continent will still be elevated, its margins will still be low and the processes of erosion, deposition and isostatic readjustment by an undertow will still tend to continue

Note that the processes just indicated explain the existence of defective density (light material) in the continent and to great depths below the surface, not by the supposition that the light material was there originally, but by the supposition that the processes of chemical change are such as to increase the volume and decrease the density of the material after it is in position as a part of a continent

In studies of the earth it is frequently assumed tacitly that the material is sensibly incompressible under changes of pressure produced by the shifting of loads, by erosion and deposition It would be as sensible as this supposition, not more absurd, to compare the material beneath an eroded surface to the contents of a vichy siphon Upon a slight reduction in pressure, of a few pounds per square inch, the contents of a vichy siphon double their volume in a few seconds After the reduction of pressure caused by the erosion of a layer a mile thick from the surface of the earth in a given region the material below to a depth of 76 miles probably changes its volume by one per cent in the course of the next few ages

Now consider the effects of the changes of temperature which would be produced by the erosion, deposition and undertow which have been indicated

Near the surface the temperature is known to increase about 1° C. for each 100 feet increase in depth below the surface At great depths the rate of increase is probably much smaller Assume that it is 1° C for each 200 feet on an average down to the depth of compensation, 76 miles Then if a stratum 1,000 feet thick is eroded from a region the temperature will be lowered under that region in the course of ages by 5° C upon an average to the depth of 76 miles Assuming that the coefficient of vertical expansion is 1 part in 60,000 per degree Centigrade, the material to the depth 76 miles will contract 1 part in 12,000 in thickness or 30 feet On these assumptions then for every 1,000 feet eroded there is a tendency to produce by cooling and contraction 30 feet of sinking of the surface, that is, one foot of sinking by thermal contraction for each 33 feet of erosion It is unimportant whether this ratio 1 33 is a close approximation It is important to note that whereas the reduction of pressure caused by erosion tends to make the material expand, the lowering of temperature caused by erosion tends to make the material contract, an opposite effect

Probably expansion by chemical change begins to occur promptly after a certain amount of erosion has occurred, since a change of pressure would probably be felt comparatively promptly even at considerable depths On the other hand, the cooling is necessarily slow and may require ages to penetrate 76 miles Hence following erosion in a given region the expansion due to chemical change will tend to begin first Later, and developing much more slowly, the contraction due to the lowering of the temperature will occur The latter may in time become as rapid or more rapid than the former, the volume may cease to increase or may even decrease, the surface may stop rising or it may even sink, and the region of erosion be changed into one of deposition.

Similarly, under a region of deposition two effects of opposite sign tend to occur.

The effect of increased pressure tends to produce chemical changes accompanied by decrease of volume and so to produce a sinking of the surface The blanket of deposited material tends to raise the temperature in each part of the material covered, to increase the volume of this material, and thereby to raise the surface The temperature effect may serve in time comparatively neutral region between the two in which neither erosion nor deposition is much in excess of the other, see Fig 2 Hence the undertow by increasing the temperature and causing a change of density may be directly effective in changing the elevation of the neutral region between two regions of deposition and erosion

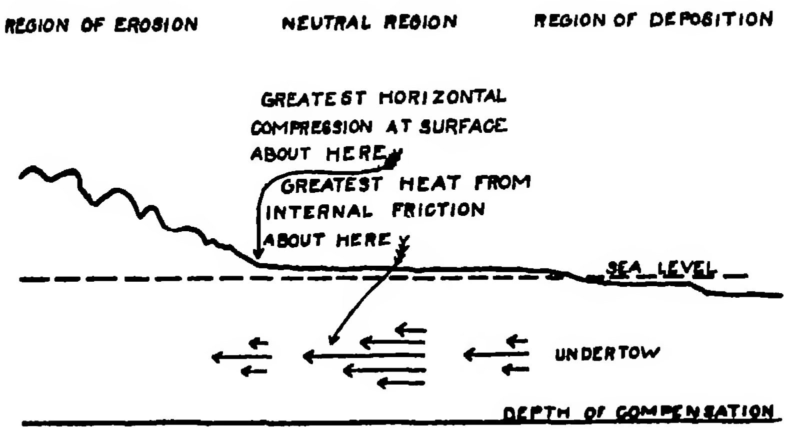

FIG 2

to arrest the subsidence caused by increased pressure or even to raise the surface and change the region of deposition into one of erosion

The changes of temperature just described are due directly to erosion and deposition If as an effect of erosion and deposition an undertow is started tending to reestablish the isostatic condition, this undertow, a flow of material presumably solid, necessarily develops considerable heat by internal friction The increase of temperature so produced tends to cause an increase of volume It may favor new chemical changes, including changes from the solid to the liquid state, which may be accompanied by a change of volume The undertow tends to be strongest not under the region of rapid erosion nor under the region of rapid deposition, but under the

Horizontal compressive stresses in the material near the surface above the undertow are necessarily caused by the undertow For the undertow necessarily tends to carry the surface along with it and so pushes this surface material against that in the region of erosion, see Fig 2 These stresses tend to produce a crumpling, crushing and bending of the surface strata accompanied by increase of elevation of the surface The increase of elevation of the surface so produced will tend to be greatest in the neutral region or near the edge of the region of erosion, not under the region of rapid erosion nor under the region of rapid deposition

There has been indicated a complicated set of changes of pressure, temperature and density and of movements of material beneath the surface, a set of changes which

have been started by erosion and deposition and continued by the action of gravitation tending to bring about a readjustment to isostatic conditions.

Attention is invited to the thought that during the actions indicated the pressure, temperature and relative movements in any small portion of the material are a function not simply of the facts at that place but also largely of the facts at many other places, some at considerable distances.

For example, in the neutral region between a region of erosion and one of deposition there may be movements beneath the surface (the undertow), changes of temperature in the flowing material, a crumpling of the surface material, changes of volume and changes of elevation of the surface, all of which are dependent primarily upon the facts in adjacent regions of erosion and deposition.

Let us limit our thoughts still to the cycle of changes which have been sketched roughly. Keep it in mind that the actions at any given point in the material depend on the facts at many other points. Keep it in mind also that a region of erosion in one age may, and often does, become a region of deposition in another, and that, therefore, the actions taking place at any instant in a given portion of the material are necessarily dependent upon the past as well as the present conditions. Is it not evident that even if the cycles of action which have been indicated were the only actions taking place in the outer portions of the earth, the resulting series of movements observable at the surface would be very complicated? Is it at all certain that under the influence of such actions the geological record at the earth's surface at the end of 50 to 100 million years would be appreciably less complicated than the geologic record which is actually before us? I think that it would be fully as complicated as the actual record.

Let me illustrate, by a single example, the kind of reasoning which the considerations just stated should lead one to avoid.

It has been stated to me that mountains are sometimes eroded to a peneplain, and that thereafter the peneplain sometimes sinks. It has been suggested to me that such a case can not be reconciled with the theory of isostasy. It is said that as the material is eroded from the surface the underlying material must increase in volume to keep the isostatic compensation complete, hence that according to the theory of isostasy a peneplain may rise but never sink.

This reasoning contains several errors. In the first place, in Fig. 1, after a portion of the surface of column *A* has been carried away by erosion and the pressure at the bottom of the column thereby reduced to less than that under column *B*, the mere vertical expansion of column *A* will not reestablish equality of pressure. The equality may be reestablished only by restoring mass to column *A* by forcing material into it from some other column. This gravitation tends to do. Secondly, when gravitation, by producing an undertow, forces material into column *A* the new material may enter by processes which increase the density of column *A*. Column *A* may thus become heavier without any raising of its upper end. An eroded surface does not necessarily rise. Thirdly, a time may come when by virtue of the lowering of the temperature by erosion the material in column *A* may increase in density by thermal contraction and the surface may thus be lowered without any masses passing to other columns. If so, the isostatic condition remains unchanged, the relative pressures at the bases of *A* and *B* remaining unchanged. Such a process

may cause a region which has been eroded from mountains to a peneplain to sink thereafter. Fourthly, such reasoning as that cited ignores the history of the region before the mountains were there. That early history is essential to a full understanding of late movements. Fifthly, such reasoning entirely ignores the relations of the region considered to adjacent regions. As the evidence shows that the material concerned in isostatic readjustment is 76 miles deep, it is but sensible to estimate that the influences concerned in any one movement of isostatic readjustment extend over horizontal distances of at least 76 miles, probably over distances as great as 200 miles Therefore, valid reasoning in regard to the peneplain in question should include a consideration of the conditions surrounding it to a distance of 200 miles, whereas in fact in the reasoning cited the surrounding conditions were entirely ignored.

How is it possible to form an estimate of the relative effectiveness of gravitation tending to produce isostatic readjustment, on the one hand, and of all other forces acting on the outer portion of the earth, on the other hand? Gravitation is the only force which continuously tends to produce isostatic readjustment. The rigidity of the material tends continuously to oppose the readjustment toward isostasy. Other forces than gravitation are equally likely to help or to oppose gravitation. Therefore, the fact that the isostatic compensation is everywhere nearly complete is a proof, first, that the material composing the outer portions of the earth has but small effective rigidity, and, second, that the forces in operation other than gravitation are relatively ineffective. If either of these propositions were untrue the present close approach to complete isostatic compensation would not exist.

Before closing let me remind you that the geodetic evidence shows that the outer portion of the earth is not a solid crust a few miles thick floating on a liquid substratum of slightly greater density.[7]

The existence of isostasy is now thoroughly established by evidence which is available in print. The time has come to speculate upon the manner in which the isostatic readjustments are produced, to look for the relations between the known condition, isostasy, and other known facts. This address is a map showing the results of a reconnaissance in this field The reconnaissance has involved much more thought than I have been able to put into words here Some of the statements have been made in rather a dogmatic form. That is simply because I have tried to draw a clear reconnaissance map with few strokes, not that I have forgotten that the field work has been merely reconnaissance. I feel confident, however, that in due course of time when careful surveys shall have been substituted for this reconnaissance, the main features of this reconnaissance map will be found to be correct.

In closing let me give you the reconnaissance map on a small scale with details omitted

Readjustment toward isostatic conditions has been in progress throughout geologic time

The differences in density involved in complete isostatic compensation are very small, usually less than one per cent., seldom more than three per cent.

With reference to such small changes of density the earth is not incompressible under the influence of stresses which are applied continuously for geologic ages.

Erosion and deposition cause changes of pressure, which in turn bring about

[7] "The Figure of the Earth and Isostasy," pp. 163–164.

changes of chemical state in the heterogeneous material within the earth such that increase of pressure in time produces increase of density, and relief of pressure produces decrease of density.

The direct effects of erosion and deposition on temperatures in the underlying material are such as to cause changes of density opposite to those caused directly by the change of pressure and probably occurring later than those caused by changes of pressure.

Gravitation tends continuously to bring about a readjustment to isostatic conditions by producing a deep undertow from a region of deposition to a region of erosion.

This undertow by virtue of heat produced by internal friction and by virtue of surface compressive stresses in the horizontal direction tends to raise the surface of the neutral region between a region of deposition and one of erosion.

The phenomena of isostatic readjustments by gravitation are complicated. Actions involved at any one spot are a function of the facts at many other places and of the facts of earlier ages.

The material in the earth to a depth of 76 miles is weak under the action of forces applied for geologic ages. The effects of gravitation predominate over those of other forces to this depth.

John F. Hayford

THE MERSHON EXPEDITION TO THE CHARITY ISLANDS, LAKE HURON

For several years the University of Michigan Museum and the Michigan Geological and Biological Survey have been cooperating in a biological survey of the state. The survey has had a small annual appropriation for this work, and has deposited the collections in the museum, but the expeditions sent out from the latter have nearly all been made possible by gifts from persons interested in the progress of the work or in the institution.

In the summer of 1910, Hon. W. B. Mershon, Saginaw, Mich., placed in the hands of the chief field naturalist of the survey, who is also the head curator of the museum, a sum sufficient to send a small party to the Charity Islands in Saginaw Bay, for the purpose of investigating the fauna and flora.

The Charities comprise a group of three small islands situated near the mouth of Saginaw Bay. The largest of these, Charity Island proper, contains about 650 acres, Little Charity Island, the next largest, about 3 acres, and Gull Island is a small projecting reef, about a quarter of an acre in extent, that is not usually shown on the maps. The group is somewhat nearer the west coast than the east. As plotted on the Lake Huron Coast Chart No. 2, of the United States Lake Survey, the distances of the larger island (where most of the work was done) from the mainland are as follows: to Point Lookout, slightly north of west, six and seven eighths miles; from Caseville, due southeast, nine and five eighths miles; from the end of Sand Point, a little east of south, seven and three fourths miles; from Oak Point, south of east, nine miles.

The islands are of interest biologically in two ways. In the first place, as they have not been connected with the mainland since glacial times, the biota must have reached them over a stretch of water at least as broad as that which now separates them from the mainland. In the second place, they are apparently upon a migration route of many species of birds.

The men engaged to do the work and the groups to which they devoted most of their time were as follows: W. W. Newcomb (butterflies and moths), N. A. Wood (vertebrates), A. W. Andrews (beetles), Frederick Gaige (ants), C. K. Dodge (plants). The museum and survey are greatly indebted to these men, for they did the field work without other remuneration than their expenses, and are now preparing their results for publication. Acknowledgment should also be made of the assistance of the light-house board, Washington, D. C., and Commander C. B. Morgan, inspector of the eleventh light-house district,

Detroit, Mich., in granting permission to work on the islands The assistance received in the field will be acknowledged in the several papers

The results of the expedition will be published in various journals and in the annual reports of the Michigan Academy of Science under the common title "Results of the Mershon Expedition to the Charity Islands, Lake Huron" As most of the field work was done in the late summer and fall, the survey plans to continue the work in the spring and early summer of 1911

ALEXANDER G RUTHVEN
UNIVERSITY OF MICHIGAN MUSEUM

ARTESIAN WATERS OF ARGENTINA

THE climate of a part of Argentina is semi-arid, and the geological formations which are regarded as Quaternary and Later Tertiary are in the western and central districts of the country saline to a degree which indicates prolonged duration of aridity The region of the pampas which covers the province of Buenos Aires and stretches northward west of the Parana does not exhibit this characteristic, it having apparently long enjoyed a more humid climate, as it does now The foot-hills of the Andes are also well watered But with the exception of these last-named regions, a great part of the country suffers from lack of good water This condition may, however, be in some measure relieved by proper development of artesian supplies Many wells have been sunk already, but without adequate geological investigation. In the pampas water is found at a general depth of 20 meters more or less, and is pumped to the surface by windmills It may be said that the development of the livestock industry of Argentina would be impossible were it not for this supply which comes from eolian, alluvial deposits of Quaternary and Tertiary age. A different geological condition exists from the Rio Colorado southward in what may be best described as northern Patagonia In that region there are local elevations occupying a middle position between the Atlantic and Pacific, composed of granites and older rocks possibly of Paleozoic age, and rising to altitudes of 300 to 1,000 meters These mountains are not represented upon any map and their distribution is not known, but they have been described by Moreno and other explorers Upon their flanks there is an extensive formation of gray sandstone which attains a thickness of several hundred feet and is very porous It slopes gently toward the Atlantic and pure water flows from it in outcrops near the coast The head of water in these strata is unknown Further south in Patagonia the central sierra is replaced by plateau country and in Comodoro Rivadavia, in latitude 46 near the coast, wells which were sunk by the government in search of water developed petroleum There is a large area in this region in which the geologic structure and the possibilities of artesian water need to be developed In the great plains east of the Andes there are glacial deposits which may furnish superficial supplies like those of the Dakotas, and the marine Tertiary and Mesozoic strata afford conditions not unlike those of southern California Here as well as in the valleys among the spurs of the Andes from Patagonia to Bolivia the geological structure is complicated and the problem of artesian water is one of peculiar difficulty as well as of great interest

Our present knowledge of these conditions rests upon reconnaissance work and the stratigraphic and paleontologic observations of the Geological Survey of Argentina No work based upon topographic maps and systematic structure has as yet been undertaken The problem is therefore one whose elements are as yet to be developed. The Argentine government is using every means to encourage settlement and development of the rich agricultural regions which lie in the zone of sufficient rainfall east of the Andes, and also the vast grazing district of Patagonia In order to afford ready communication it is building railroads at great national expense and operating them The need of pure water for locomotive use as well as for other purposes has thus been made critically evident,

and the Minister of Public Works, Senor Ramos Nexia, has adopted a plan for making surveys for the determination of artesian water conditions along the lines of national railways. He contemplates topographical and geological surveys of a character similar to those executed by the U. S. Geological Survey, from which he derived the initial suggestion. He last summer applied to the U. S. government for the services of a geologist and such assistants as he might need, and our government has responded cordially to that request. Mr. Bailey Willis has accordingly entered into a contract for the term of two years, to execute topographical and geological surveys for the specific purpose of ascertaining artesian water possibilities in those districts which the minister may designate. With him are associated Mr. Chester W. Washburne, of the U. S. Survey, Mr. J. R. Pemberton, of Stanford University, and Mr. Wellington D. Jones, of Chicago University, as geologists, and Mr. C. L. Nelson and Mr. W. B. Lewis, as topographers, and the party sails shortly for Argentina to enter upon the work. While these surveys have a specific purpose, their possibilities of usefulness in developing the natural resources and encouraging settlement in the regions surveyed will not be overlooked, and the work will be founded on these scientific studies, upon which alone practical conclusions can safely rest. Thus it is hoped that a definite contribution to knowledge in geography and geology may be made.

It is desirable to point out that the Argentine government has a geological survey which has been in existence since 1903 in its present organization and which dates back half a century as a bureau of mines. It is under the direction of Senor E. M. Hermitte, who is assisted by Messrs. Bodenbender, Keidel and Schiller, three German geologists who have done excellent stratigraphic and paleontologic work, particularly in districts of the central Argentine Andes. They have unfortunately not been supplied with maps. The established Bureau of Mines, Geology and Hydrology is under the minister of agriculture. The surveys which are about to be made are undertaken by the minister of public works. The two operations are thus officially distinct, but it is hoped and anticipated that they may be mutually helpful.

THE ENGINEERING BUILDING OF THE UNIVERSITY OF CINCINNATI

The new $300,000 engineering building, and the new $150,000 power plant of the University of Cincinnati are rapidly nearing completion. The engineering building is of reenforced concrete and stone, four stories in height, built to accommodate five hundred students, and inasmuch as the greater number will be cooperative students, the building will accommodate one thousand.

Among the main features of the building will be a large laboratory 200 × 40 feet in size. This laboratory will be surrounded by balconies, which will give a much larger floor space than is indicated by the dimensions of the room itself. In addition to this there will be a large general club room for the students taking the regular engineering courses. There will also be a large consulting library, solely for the use of the College of Engineering.

The building will be fire-proof throughout and of the best possible construction. One marked feature of the building will be the absence of a great mass of heavy machinery which is usually found in engineering colleges. The students will possess the unique advantage of having at their disposal the use of the latest and most improved machinery in all of the different manufacturing industries having plants in the city of Cincinnati. They will gain their knowledge of the different operative processes at first hand in the great manufacturing establishments, for which Cincinnati is famous. This condition has permitted the use of space which would have otherwise been occupied by machinery for extensive scientific and research laboratories.

The power plant is one of the most extensive and thoroughly equipped in the country, and has been built to meet the needs of a growing university for many years to come. It will supply heat, light and power for all of the different buildings of the university.

One marked departure from the customary arrangement of university buildings will be

found in the class-room facilities in the new engineering building. Inasmuch as the building has been erected mainly for the use of the rapidly enlarging cooperative department, it was felt by Dean Schneider that the old arrangement of class rooms was inadequate to meet the needs of the mature men who constitute a large proportion of the university student body These men come from the various shops and large establishments of the city to the college, and in their daily experience in actual productive work, they have been confronted by many problems, not alone of theory, but of practise, and these problems have suggested to them certain very definite questions which they bring from the shops to the college for answer by their instructors It was felt that a change in the ordinary class-room work and arrangement was needed to meet these new conditions Each section will have a room which will be wholly its own. This room will be furnished with a table 5×10 feet, comfortable chairs, drawing tables, drawer lockers and magazine racks Each group will have one such room, which will serve the dual purpose of club and class room.

The purpose will be to make these rooms not only places for recitation and instruction, but also sub-social centers They will contain everything needed to satisfy the social needs of each section, and during the time when classes are actually being conducted in this room, the teacher and the men in the class room will sit around the large table and the practical and theoretical questions which the students have asked will be discussed in open session This is a marked innovation in interior college arrangements, but the whole plan of the engineering college is being evolved to meet the special needs of the cooperative system, and any change whatsoever which promises to more satisfactorily meet the needs of a student body such as will occupy this building, will be thoroughly tried out before its adoption or final rejection.

THE INTERNATIONAL SCHOOL OF AMERICAN ARCHEOLOGY AND ETHNOLOGY

THE International School of American Archeology and Ethnology was inaugurated in the City of Mexico on January 20 The founding patrons of the school are the government of the United States of Mexico, the government of Prussia, Columbia University and Harvard University. The University of Mexico has placed at the disposal of the school rooms in which classes may be held, and will facilitate access to libraries, museums, institutes and other scientific centers in which are pursued studies like those of the school, and will aid in the support of the school with an annual subsidy of $6,000 Each patron will in turn appoint and pay a director of the school, and will also allot fellowships which will be sufficient to cover the expenses of board and lodging and transportation of a fellow In accordance with the statutes the government of Prussia has appointed as director Professor Eduard Seler, director of the section of anthropology and archeology in the Royal Museum at Berlin, who has already made extensive researches in Mexico He will hold office for one year, and will be aided by Professor Franz Boas, of Columbia, during his presence in Mexico as professor of anthropology at the National University Two appointments to fellowships have been made, Dr Werner Von Hárchelmann by Prussia, and Miss Isabel Ranives Castaneda by Columbia University

All the explorations and studies of the school are to be subject to the laws of the country in which the work is undertaken, and all objects found in investigations or explorations will become the property of the national museum of the country in which the studies are carried out In case similar specimens of the same kind of object are discovered duplicates will be given to the patrons who supply the necessary funds for the exploration Most of the explorations will be conducted in the rich fields of Mexico, and the government of that country has already given the necessary authorization for the investigations which will soon be begun and are certain to produce interesting and valuable results.

SCIENTIFIC NOTES AND NEWS

SIR JOSEPH LARMOR, Lucasian professor of mathematics at Cambridge University and

secretary of the Royal Society, has accepted an invitation to become the unionist candidate for the vacancy in the parliamentary representation of Cambridge University.

The Belgian Royal Academy of Sciences, Letters and Arts has awarded to Dr. L. A. Bauer, of the Carnegie Institution, the Charles Lagrange Prize for the period of 1905–08, of 1,200 francs, on account of his various researches in terrestrial magnetism.

Dr. Hideyo Noguchi, associate member of the Rockefeller Institute for Medical Research, received in December, 1910, from the Japanese government the honorary title of Professor (Igakuhakushi).

Professor Jacques Hadamard, of the Collège de France, has accepted an invitation from Columbia University to give instruction in mathematics at Columbia for a period of four to five weeks in the autumn of 1911. He will conduct one course in pure mathematics and one in mathematical physics.

It is reported that the Krupp Society has given Professor Emil Wiechert, of the University of Gottingen, 10,000 Marks to enable him to conduct experiments in aerodynamics, and also 6,000 Marks to Professor Leopold Ambronn, of the same university, for the construction of a new photographic apparatus.

The American Philosophical Society at a recent meeting appointed a committee to memorialize congress with a view to founding a National Earthquake Laboratory at Washington. This committee consists of Dr. Charles D. Walcott, secretary of the Smithsonian Institution, chairman; Professor H. F. Reid, Johns Hopkins University; Professor William H. Hobbs, University of Michigan; Dr. R. A. F. Penrose, Philadelphia, and Professor T. C. Chamberlin, University of Chicago.

It is announced that Baron Reinach has provided the Frankfort Physical Society with the funds necessary to establish a seismological observatory on the Feldberg, in the Taunus range. Dr. F. Linke will be the director of the observatory.

Professor F. Smith and Mr. F. A. Loew, of the University of Illinois, will this summer be associated with Professor J. E. Reighard at the Biological Station of the University of Michigan at Douglass Lake.

C. L. de Muralt, recently appointed professor of electrical engineering at the University of Michigan, becomes editor of the *Railway Electrical Engineer*. This journal is the official organ of the Association of Railway Electrical Engineers.

Dr. J. J. Davis, of Racine, Wis., who has devoted a large amount of time to the study and collection of parasitic fungus flora of Wisconsin, has been appointed curator of the herbarium of the University of Wisconsin. On their transfer to the new biological building, the botanical collections will be provided with new and better quarters for work, and a complete reorganization of the museum is planned.

Fourteen Harvard professors will be absent during the second half of the current academic year. They include Professors C. L. Jackson, of the chemistry department; Hugo Munsterberg, of the philosophy department, who is serving as exchange professor at the University of Berlin; J. L. Love, of the mathematics department; C. L. Bouton, of the mathematics department; W. Z. Ripley, of the department of economics; R. B. Dixon, of the division of anthropology, and C. R. Sanger, of the chemistry department.

The following officers were elected at the recent annual meeting of the Royal Meteorological Society: *President*, Dr. H. N. Dickson; *vice-presidents*, F. Druce, H. Mellish, R. G. K. Lemfert, Colonel H. E. Rawson, C.B.; *treasurer*, Dr. C. Theodore Williams; *secretaries*, F. C. Bayard, Commander W. F. Caborne, C.B.; *foreign secretary*, Dr. R. H. Scott, F.R.S.

The Nashville section of the American Chemical Society held its organization meeting at Furman Hall, Vanderbilt University, on January 25. After the adoption of a constitution the following officers were elected: *chairman*, W. L. Dudley; *vice-chairman*, J. I.

D Hinds, *councillor*, R. W. Balcom, *secretary and treasurer*, L J Desha. Dr W. L Dudley gave an informal talk on the "Action of Wireless Waves on Rarefied Gases" The regular meetings of the section will be held on the third Friday of each month

Dr H W. Wiley, chief chemist of the Department of Agriculture, Washington, D. C, delivered an address at Syracuse University on February 1 upon "The Services of Chemistry to the Public Welfare" The meeting was held in the Bowne Hall of chemistry under the joint auspices of the Syracuse Chapter of Sigma Xi and the Syracuse Section of the American Chemical Society

Professor C K Leith, of the University of Wisconsin, gave a lecture before the advanced students in geology at Northwestern University on January 26 His subject was a comparison of the origins of the iron ores of the Lake Superior region, of Cuba and of Brazil

A lecture on electric oscillations and their application to wireless telephony was delivered before the chapter of Sigma Xi at Purdue University, LaFayette, Ind, January 28, by Professor C M Smith, of the department of physics of that university Professor Smith explained the theory of wireless telegraphy and telephony and pointed out the entirely different conditions necessary for wireless telephony as compared with wireless telegraphy The lecture was illustrated by a large number of experiments showing the analogy between electric and sound waves and was concluded with a demonstration of the singing arc lamp which reproduced very clearly a band selection through the agency of a phonograph and microphone located in a distant room

At a meeting of the Royal Geographical Society on January 16 Dr Johan Hjort gave a detailed account of the Michael Sars North Atlantic deep-sea expedition of 1910, which he, with Professor H. H. Gran, Dr. Helland-Hansen, Mr. E Koefoed and Captain Thor Iversen, undertook at the suggestion and at the expense of Sir John Murray, who himself accompanied them

Dr. Hans Grether, of Karlsruhe, Germany, has been appointed a special lecturer in McGill University and is giving in the graduate school, during the present session, a course of advanced instruction in the "Computation of secondary stresses in bridge trusses and other framed structures" The following gentlemen will act as special lecturers in the course on economic geology at McGill University during the present session R. W Brock, Esq, M A, director of the Geological Survey of Canada, Dr J D Irving, professor of economic geology, Yale University, and O E LeRoy, Esq, M Sc, of the Geological Survey of Canada

A state Biological Survey has been organized at the University of Colorado, the work being in the hands of a committee consisting of Professors F Ramaley, T D A Cockerell and J Henderson The work of such a survey has been carried on for a number of years past, but until now there has been no definite organization The work includes fossil as well as living species of plants and animals

The British Treasury has, on the recommendation of the development commissioners, made a grant to the Board of Agriculture and Fisheries from the development fund of £40,000 for the ensuing year for the encouragement of light horse-breeding in Great Britain

The third semi-annual meeting of the American Institute of Chemical Engineers will be held at Chicago, Ill, June 21 to 24 Arrangements will be made to visit a number of the large technical plants in the vicinity The committee on chemical engineering education and standardization of boiler tests will have important reports to present The program of papers will be announced later

The first Universal Congress of Races will be held in London from July 26 to 29, 1911, to discuss the general relations between western and eastern peoples.

A course of nine public lectures on problems of psychology have been given at Columbia University, as follows·

January 31—"Traits of Dreams," Professor C. E. Seashore, University of Iowa.

February 1—"Social Psychology," Professor Charles H. Judd, University of Chicago

February 2—"Memory and Imagination," Professor E. B. Titchener, Cornell University

February 3—"Frailties of Imageless Thought," Professor J. R. Angell, University of Chicago

February 4—"The Standpoint and Scope of Social Psychology," Professor Mary Whiton Calkins, Wellesley College

February 6—"The Psychology of Dream States," Professor Joseph Jastrow, University of Wisconsin

February 7—"The Rôle of the Type in Simple Mental Processes," Professor W. B. Pillsbury, University of Michigan

February 8—"The Ontological Problem of Psychology," Professor George T. Ladd, Yale University

February 9—"Some Psychological Topics Emphasized by Pragmatism," Professor Josiah Royce, Harvard University

The new Oceanographic Institute, which Prince Albert of Monaco has erected on a part of the site of the old convent of the Dames de Saint-Michel in the Rue Saint-Jacques, was formally inaugurated on January 23. We learn from the London *Times* that the opening ceremony was performed by Prince Albert in the presence of President Fallières, M. Emile Loubet, members of the government and the principal dignitaries of the university and city of Paris. In his inaugural address Prince Albert explained the motives which had prompted the foundation of the new Institute in Paris and the purpose which he had designed it to fulfil as the complement of the Oceanographic Museum that he had founded at Monaco last year. The minister of public instruction, on behalf of the government, the president of the Academy of Sciences, on behalf of the French Institute, and the vice-rector of the university each returned thanks to Prince Albert for his munificent foundation. The new institute is at once French and international in character. This latter aspect of the foundation is marked by the presence on the committee of Sir John Murray, Professor Buchanan, Professor von Drygalski, Dr. Nansen and other foreign men of science. In addition there is an administrative council composed of French men of science. The institute is designed to work in intimate cooperation with the museum at Monaco, where laboratory work will be conducted, while in Paris lectures on the principles of oceanography will be delivered.

The following resolutions favoring a federal grant to elementary and secondary education were passed unanimously by the house of representatives of the Illinois legislature on January 18.

Whereas, The legislature of Illinois by the joint resolution of February 8, 1853, was the first among American legislatures to petition the congress of the United States to make a grant of public land for each state in the union for the liberal endowment of a system of industrial universities, one in each state, to promote the more liberal and practical education of our industrial classes and their teachers; and,

Whereas, The congress not only made a liberal grant of land in the year 1862 for this purpose but has also followed up this policy once begun by still more liberal appropriations for the support of higher education in agriculture and the mechanic arts, resulting in the great chain of colleges for agriculture and the mechanic arts to be found in every state and territory in the union, and,

Whereas, The time has now come for the adoption of a similar policy in the field of elementary and secondary education therefore, be it

Resolved, by the house of representatives of the state of Illinois, the senate concurring herein, That the congress of the United States be respectfully petitioned to appropriate annually to each state and territory in the union a sum equal to one dollar per head of the population of said state or territory as ascertained by the last census, for the purpose of establishing, maintaining and extending in the elementary and secondary schools of said states and territories, while not excluding other elementary and secondary subjects, such practical, industrial and vocational training, including agriculture, the mechanic arts, domestic science, manual training, commercial subjects and such instruction in other similar subjects of a practical nature as the interests of the community may seem to demand; and

Resolved further, That our senators in congress be instructed and our representatives be requested to use their best exertions to procure the passage of a law of congress donating said sum to each

state and territory in the Union for said purpose; and

Resolved further, That the governor of this state is hereby requested to forward a copy of the foregoing resolutions to our senators and representatives in congress and to the executives and legislatures of each of the other states and territories, inviting them to cooperate with us in this meritorious enterprise

ACCORDING to a statement by Mr. Ray Priestley published in the papers before the departure of the *Terra Nova* for the Antarctic, an important geological discovery was made during Sir Ernest Shackleton's expedition Mr. Priestley, who is now engaged with Captain Scott's Antarctic expedition, and who had for some months been collaborating with Professor David at Sydney in arranging a memoir of the geological work of Sir Ernest Shackleton's expedition, states that he discovered a small piece of rock on the Beardmore Glacier which now upon full examination proves to belong to the Cambrian limestones It appears that a similar formation has in recent years been discovered in South Australia by Mr Griffith Taylor, who is also a member of Captain Scott's scientific staff The fossils found both in the latter and in the Antarctic specimens are identical, and the inference is that at a not very distant past the Antarctic was united to the continent of Australia The fossils referred to are the immediate predecessors of corals and sponges

UNIVERSITY AND EDUCATIONAL NEWS

A GIFT of $300,000 by Mrs. Russell Sage to Cornell University is announced. The money is to be used for a new dormitory for women students, to be known as the "Prudence Risley Hall" in honor of Mrs. Sage's mother.

THE old Philadelphia Dental College at Eleventh and Clinton Streets, which was purchased several months ago by Jefferson Medical College for $45,000, after remodeling will become the Daniel Baugh Institute of Anatomy.

AN increase in the income and in the building fund of the University of Wisconsin on the basis of a growth of 25 per cent. in the number of students in the last two years and of the constantly growing demand on the part of the people of the state for expert assistance from the university, is provided for in a bill introduced in the state legislature It provides for changing the present two sevenths of a mill tax on the assessed valuation of all property of the state for maintaining the university to three eighths of a mill. This will increase the general university income approximately from $750,000 a year to $1,000,000 a year For new academic buildings and permanent improvements the proposed legislation appropriates $300,000 a year, of which $50,000 annually is set aside for the purchase of books, furniture, apparatus and equipment. The remaining $250,000 a year is to be used for the construction of academic buildings, in the order of their greatest need and for the enlargement and repair of present buildings. For the construction and equipment of women's and men's dormitories the university bill provides for an annual appropriation for four years of $250,000 Out of this $1,000,000 a woman's dormitory is to be built first, then a commons and union for men, and finally dormitories for men. The university extension would have $100,000 next year and $125,000 the following year. This is an increase of $50,000 a year over the present appropriation. For agricultural extension, including traveling schools of agriculture and lectures and demonstrations throughout the state, $40,000 is provided, an increase of $10,000 over the present amount

THE regents of the University of Michigan have applied to the legislature for a grant of $250,000 for a science building The need for more adequate accommodations for the natural sciences has been felt for a number of years, and was the subject of a memorial to the regents, by the departments of botany, zoology, geology, mineralogy and forestry, in 1907. The congestion of that time has steadily become worse with the increase of students, and only slight possibility of expansion with present buildings In 1908 the faculty of the entire literary department unanimously adopted a resolution to the effect "that in the opinion of this faculty, the greatest present

need in the material equipment of the department of literature, science and the arts is a new building for the natural sciences."

DISCUSSION AND CORRESPONDENCE

UNIVERSITY FELLOWSHIPS

After reading the address of Dr. Jordan recently published in Science, I desire to enter a protest against some of his statements. I have been for many years in touch with graduate students, and have been moved with a keen desire to induce them to enter the teaching profession. I thus know of the difficulties they face and why many of them fail to fulfill the hopes I had in them. I agree with Dr. Jordan that we are not producing the scholars we should, but in the diagnosis of evils we differ. In his address he comes back again and again to the fellowship system and talks touchingly of the starving doctor of philosophy. In my opinion, the starving doctor is a figment of the imagination. It is the rapidity of promotion, not the lack of it, that ruins promising investigators.

The University of Pennsylvania has had a system of fellowship long enough to make its effects apparent. Twenty-four Harrison fellowships have been granted annually for fifteen years. Few of the fellows were, however, graduates of Pennsylvania. The effect of this will be apparent when it is recognized that from the fellows instructors are chosen and from them in turn the professors come. Practically all the instructors and younger professors are graduates of other colleges. Our young men are a cosmopolitan body representing nearly every college and university in the country. The result has been a transformation of the university in a deeper and more vital way than any other of our important changes. Besides these fellows who have become teachers there has been another group coming from the smaller colleges where they were instructors and who have returned to them after a couple years' study here. These two groups account for nearly all our former fellows.

The following table gives the present occupation of all who have been fellows.

Professors and instructors in universities and colleges	107
Normal and secondary teachers	31
Literary work	5
Business and business experts	8
Government experts	6
Chemical experts	4
Social work	7
Ministers	5
Students	10
Deceased	8
Unknown	2
Total	193

This does not look like starvation. If we had double the number of fellowships we could double the service we render to our own and to sister institutions without overstocking the market. The fact is a good instructor pays his way everywhere. It is the professor that needs endowment.

Where then is the trouble if it is not in this quarter? Here again I shall turn to my own experience, which, however, I believe is that of many others. I find among the fellows a man of promise. He is made assistant at $800 a year, then instructor at $1,000, which is steadily increased until at thirty he is earning $1,500. Now comes the test under which so many break down. He has published a thesis, written several articles, and has become a proficient teacher. This makes him a man of the kind that college presidents want and friends praise. It is one of the peculiarities of college presidents that they want "men of promise," they never seek for "men of deeds." This young man should settle down on his $1,500 a year and do work that would advance his science. But the attractions of salary and the flattery of friends are too much for him. He drops his original work for more pay and finds that hastily constructed books help him along more rapidly than original work. This is the last of him so far as science is concerned. Let me give a couple examples. A young instructor was pushed along until he had the $1,500 a year. He then received an offer of $2,500 from another college. I talked to him in this way: "You are familiar with the courses you give and your hours are reasonable. Now is the

time to use your leisure to do original work The next five years will settle what your scientific standing will be See that you make good I can not get for you an increase of salary, but I can get for you every facility for good work" I thought I had my man, but he came to me a couple days later saying he had decided to go, as his wife thought she could not live on $1,500 a year As a second case I take that of a young man in another institution in whose work I became interested When a book of his appeared, I wrote him that I was sorry he printed it It did not fulfil the expectations I had of him, and I believed no man could afford to be the author of a useless book He replied that he was glad others were not of my opinion and sent with the letter several laudatory clippings from papers and eulogistic letters from professors with reputation This, of course, was a great victory and in a way I admit he was right, for the book brought him a call to a leading university. But a book of promise is yet to come This, not starvation, is the road to ruin Young men are not spoiled as fellows, but as assistant professors A call means new responsibilities, the breaking up of old habits and a loss of self-discipline The new president calls him a second Agassiz, the university press bureau spreads laudatory notices of him in the local press and the alumni take a hand in extension of the fame of the new genius

Dr Jordan tells us that he has been working for others the greater part of his life and that he is disappointed in the results. But for whom has he been working—for fellows or for assistant professors? There are no fellowships at Stanford University. If he would go over his cases, he would, in my opinion, find that he, like other college presidents, has been dragging into the lime light young men that it would have been better to have let alone Each university should build up its faculty quietly from its fellows instead of running press bureaus to laud immature men Scholars are not born, they are made by their environment

No one is worth keeping who will not halt long enough on $1,500 a year to do good work The assistant professorship is an unearned entrance to the halls of learning. If faculties would agree that no one should have the title of professor until it was fully earned, the increase of true learning would be possible Scholarship is made by hard work, and comes only with gray hairs If a man is wanted from another university take its best. Young men should be left alone until they are fully developed before transplanting them.

University of Pennsylvania

To the Editor of Science: In response to a recent friendly note from Dr Edmund B Wilson let me say No money could be better spent than that used for the fellowship which enabled Wilson to walk and work with Brooks and Martin and Remsen But too much such money is used to hire mediocrity to make diagrams for pedantry

Our scholars must in some degree be descended from scholars Relatively few of our teachers have the personality which befits the leader in an intellectual school The scholar should be free to seek such leadership, and our present fellowship machinery tends, on the whole, to confuse rather than to help

David Starr Jordan

THE ARIZONA PASSENGER PIGEONS

The passenger pigeon is now generally believed to be extinct in a wild state, and of those formerly living in confinement only a single survivor, in the Zoological Garden at Cincinnati, remains Under these circumstances reminiscences of its past history naturally find place in ornithological and other journals, based on the recollections of observers still living or gleaned from the published narratives of early travelers and explorers of the birds' former range, some fifty pages of such matter having appeared in the last two numbers of *The Auk* alone Among recent contributions to passenger pigeon lore is Dr McGee's "Notes on the Passenger Pigeon," published in a recent number of Science[1]

[1] Vol XXXII, pp 958–964, December 30, 1910

Dr. McGee's paper is divided into two parts, the first giving his recollections of the great abundance and habits of the passenger pigeon as seen by him in eastern Iowa nearly half a century ago, the other an account of birds supposed to be passenger pigeons seen in arid southwestern Arizona as recently as 1905. His account of the abundance of these birds during the spring migration in eastern Iowa "in the sixties and early seventies" of the last century is a fact of great interest and is in accord with what is known to have occurred in the eighteenth and the early part of the nineteenth centuries in states further to the eastward. But the habits of the Iowa pigeons, as here detailed, during the breeding season and until and during the fall migration, are wonderfully suggestive of the habits of the mourning dove, and depart considerably from the habits of the passenger pigeon as observed and repeatedly recorded at points further eastward, as, *e g*, their laying two white eggs, living in family groups during and after the breeding season, and in this manner taking their departure southward at the approach of winter

The second or Arizona part of the paper is entirely contrary to our previous knowledge of the distribution of the species, and especially contrary to everything known of its breeding area It has not heretofore been recorded as occurring west of the eastern border of the plains, while its known breeding area was the transition zone of the east. To enable a bird with these geographical and physiological restrictions to pass the hot season and rear its young in the subtropical Lower Sonoran zone of southwestern Arizona implies a most wonderful range of adaptability, and one quite unparalleled in our present knowledge of bird life Not that some species of birds, the mourning dove among others, do not have breeding ranges that cover the greater part of North America, and seem equally at home, even in the breeding season, in regions as unlike as the humid wooded districts of the eastern states and the arid southwest, but there are others, like the passenger pigeon, which are restricted to a particular type of country, especially during the breeding season. From their known distribution, habits and food requirements, one would almost as soon expect to find a colony of ptarmigan, an alpine or semi-arctic bird, in Florida as passenger pigeons in the arid, almost forestless Lower Sonoran zone of southwestern Arizona. The passenger pigeon occupied the wooded districts of eastern North America, breeding from eastern Kansas, northern Mississippi, Tennessee, Pennsylvania and New York northward to western Mackenzie, central Keewatin, central Quebec and Nova Scotia, and usually in large colonies, it being at all times preeminently gregarious. If formerly found west of the great plains, it is very strange that none of the scores of ornithologists who have either lived for many years in the general region of Arizona and New Mexico or have during the last two or three decades thoroughly explored it in all parts, down to and along the Mexican border, have ever collected a specimen anywhere in this whole area that has been identified by a competent ornithologist as a passenger pigeon Again, Dr McGee's account of the nesting and other habits of the birds he took to be passenger pigeons at Tinajas Altas in Arizona are not incompatible with those of the mourning dove, its little brother, known to be of common occurrence in just the situations described Furthermore, the bird there known as the "Sonora pigeon," and referred to by Dr. McGee as "seen singly and by twos and threes, either distant or in flight," and "noted as resembling the passenger pigeon," is the white-winged pigeon (*Melopelia asiatica*, formerly *M. leucoptera*) "The Sonora pigeon (at least the bird observed at Tinajas Altas) differs so widely as to be readily distinguishable from the mourning dove," and of course also from the passenger pigeon. It is extremely to be regretted that "unexpectedly hasty abandonment of the camp unfortunately prevented preservation of skins of the birds," for while no one will doubt the author's sincerity and conscientiousness in placing on record his recollections of these birds, it is certain that ornithologists will desire more

substantial evidence of so improbable an occurrence as the breeding of the passenger pigeon in arid southwestern Arizona before they will be willing to accept these observations as a part of the history of a now practically extinct species If specimens of the birds in question had been obtained and identified by competent authority, it would doubtless have saved burdening the literature of the wild pigeon with another questionable record, and one that may prove extremely difficult to eliminate.

J. A. ALLEN

ON THE TRANSFERENCE OF NAMES IN ZOOLOGY

As the preparation of an official list of *nomina conservanda* is now under consideration by the International Commission on Zoological Nomenclature it may not be out of place to call attention to a point that seems to me of prime importance in this connection, although it has received little notice from recent writers on nomenclatorial reform

It is simply this—while the rejection and replacement of familiar names for well-known animals is, of course, an inconvenience to zoologists, it is a trivial matter in comparison with the grave possibility of confusion that arises when the names are used in an altered sense In the former case we merely multiply synonyms, and, unfortunately, they are so numerous already that a few more hardly matter; in the latter case there is a real and serious danger of ambiguity. Thus, at present, a writer who mentions *Trichechus* may be referring either to the Walrus or the Manatee, *Simia* may mean either the Orang or the Chimpanzee, *Cynocephalus* may be either a "flying Lemur" or a Baboon, and so on through all the great groups of the animal kingdom till we come to *Holothuria* which may refer either to a sea-cucumber or to a Portuguese man-of-war. Cases like these seem to me to be on an entirely different plane, as regards practical importance, from those in which an old name is simply rejected; even if the shore-crab is to be called *Carcinides* for the future we have only the additional burden of remembering that it was once called *Carcinus*.

A striking (if somewhat exceptional) instance of the pitfalls that are in preparation for future students is found in the section on Crustacea in Bronn's Thierreich (Bd V., Abth ii) On p 1056 there is an allusion to "*Astacus*" and on the following page to "*Astacus* (= Homarus)." In the bound volume (unless the part-wrappers have been kept in place) there is nothing to show that a change of authorship intervened between these two pages and that, while the second "*Astacus*" refers to the lobster, the first indicates the crayfish

If the International Commission could be persuaded to consider first those names that are threatened with *transference*, before proceeding to deal with those that are merely in danger of *replacement*, they would, I believe, secure the support and cooperation of many zoologists who have doubts as to the practicability of the schemes lately put forward.

SCIENTIFIC BOOKS

African Mimetic Butterflies. By H ELTRINGHAM Oxford, Clarendon Press. 1910.

The remarkable resemblances often observed between insects of different genera, families or even orders, have long attracted the attention of naturalists. In some, probably many, cases the explanation may be found in parallel variation, or similar conditions of life. Such explanations do not go far into the heart of the matter, but they are satisfying to those who like to give a "reason" for everything. Bates, who was so familiar with the insect-fauna of the Amazons, hit upon a more special "reason" for resemblances observed by him. This was, in short, that certain species which were edible simulated others which were distasteful and so gained protection. The subject was taken up by Wallace and other naturalists, and soon a large body of evidence was available, especially in relation to butterflies. It was proved to be a fact that certain

forms were disliked by birds and other natural enemies, it was shown that young birds did not instinctively reject these insects, but that after having tried and found them nauseous, they avoided them subsequently. It was then not difficult to see that if an edible species came to sufficiently resemble an inedible one it would be often taken for it and so escape. At this point it was observed that sometimes there were two or more butterflies very much alike, but all inedible. Fritz Muller pointed out that there would be gain in this, since the experience obtained in tasting one might suffice to cause a bird to reject all subsequently, whereas if they were all alike, each would separately have to pay its tribute to inexperience. Thus there were recognized two sorts of "mimicry," called the *Batesian* and *Mullerian*, respectively.

Examples of these phenomena have especially been observed in the tropics, where substantially the same conditions have existed for long ages, and living things have had time to develop some very nice adjustments and interrelations. In the volume just issued, Mr. Eltringham has taken up the mimetic butterflies of Africa, and has covered the ground so well that any reader may gain a good knowledge of the main facts without access to a collection of African specimens. There are given no less than 176 excellent colored figures illustrating the different species, varieties and sexes, while in the text each one is discussed at some length. There are also sufficient bibliographical references. In addition to the matter indicated by the title, there is a good general discussion of the whole subject of mimicry, and a summary of the evidence relating to natural enemies. Thus Mr. Eltringham's book may well serve as a guide to those taking up the subject and will be found useful in biological departments of universities, where "mimicry" is discussed along with other biological theories.

A special chapter is devoted to objections to the theory of mimicry, but those wishing to see the strongest adverse arguments should consult Professor R. C. Punnett's paper on mimicry in Ceylon butterflies, recently (September, 1910) published in *Spolia Zeylanica*, Vol. VII. Professor Punnett spent two months in Ceylon investigating some well-known cases, and came to the conclusion (or fortified a conclusion previously reached?) that the phenomena should be explained in quite another manner. Professor Punnett, like Mr. Eltringham, gives us admirable colored figures, and his discussion is most interesting. Some of the points brought forward are the following: (1) In Ceylon birds seem not to be serious enemies of butterflies. The chief enemies are apparently lizards and Asilid flies, and these appear to lack discrimination. (Experiments with a lizard were made.) (2) In various specified cases, the "model" and "mimic" do not occupy the same area to any extent, or the "model" is scarce when the "mimic" is common, a condition irreconcilable with the Batesian theory. (3) The resemblance is often imperfect, and when the flight of the insect is different it seems unlikely that they should be confused.

Against evidence of this sort may be placed the abundant data of Wallace, Marshall, Trimen and others, who have spent long years in the tropics, instead of a short two months. It may be reasonably urged, however, that if in only a few cases it can be demonstrated that "mimicry" has a meaning quite different from that assigned by Bates and Muller, serious suspicion is thrown on the whole theory or group of theories. Professor Punnett, long associated with Professor Bateson, is of course well known as an ardent Mendelian, and it is not a surprise to find at the end of his paper a Mendelian interpretation of mimicry. As he states, breeding experiments are urgently required, but judging from the classic experiments of Doncaster on *Abraxas*, he formulates an hypothesis to account for the polymorphism of mimetic *Papilio* in Ceylon. We can not take the space here to copy his tables, but the results he gets appear to coincide with the facts. Incidentally he cites the case of *Colias edusa*, in which the pale *helice* form of female, crossed with a normal male (necessarily so, as *helice* occurs only in the female) gave females of

both *edusa* and *helice* types He remarks that the fact that *edusa* ♀ can come from *helice* appears to disagree with his hypothetical scheme, but he adds that the typical female differs from the male, and suggests that there *may* be or have been a possible "*a* type" of female resembling the male (such a type is well known in the *Papilio* under discussion) It is interesting to be able to state that the hypothetical "*a* type" of female *C edusa* is actually known, and may be found mentioned in *Entomologist*, 1889, p 26

I can not help thinking it probable that whether or not the precise Mendelian hypothesis offered by Professor Punnett is justified by subsequent research, the facts will be found to be very much as he has postulated I do not think, however, that the theory of mimicry is thereby contradicted According to the old view that all organisms are everywhere varying (aside from non-inherited environmental effects), and that natural selection is necessarily in continuous operation to keep them constant or to modify them as needed, it must be confessed that some of the observed facts are hard to interpret According to the newer view that "original variations" happen at relatively rare intervals, and that a stable type once produced may continue indefinitely if not discriminated against, the matter assumes a very different aspect Consider the great antiquity of insect genera, as shown by fossil remains; consider the kaleidoscopic changes in insect-type producing innumerable species often without material advance in the general type, with all this time and change there must have been produced many pairs of more or less unrelated species resembling one another When this resemblance has been advantageous it has been preserved, while other forms have died out, and hence to-day the proportion of such cases is vastly greater than we could expect from chance coincidence It is not necessary that everywhere and at all times mimicry should be functional, the evidence seems to show that it generally is, and that is sufficient Indeed, if a type has been preserved because of its ability to "throw" mimetic forms, it is likely enough to continue to do this, even in places where this is unnecessary

Those who are confronted by the vast array of insect species rarely think of the unseen gaps in the ranks These may perhaps be best appreciated by considering the fauna of the Hawaiian Islands, as elucidated by Sharp, Perkins and Walsingham Here we have large genera with multitudes of allied species, no doubt the result of the immigration in ancient times of single types of a few groups Comparatively free from the stress of competition these Hawaiian groups have, as it were, nearly their full membership, on continental areas only remnants usually remain

Thus I think that the newer work on heredity, read aright, only strengthens the theory of mimicry, by relieving it of a load it was ill-fitted to carry I do not see any other plausible way of accounting for the facts, unless it is by supposing that similar environments give rise to similar modifications of the germ-plasm This idea loses support when we remember the cases (*e g*, in butterflies and bees) in which the same superficial appearance is due to entirely different structures

It may still be debated whether natural selection has had much to do with the production of mimetic forms, in the sense of bringing about the *accumulation* of favorable variations For my own part, I can not doubt that this cumulative effect of selection is real, and is a necessary cause of the more striking and complex instances of mimetic resemblance The rarity of original variations, while great enough to relieve selection from the necessity of acting continuously on all characters, is doubtless not so great as to prevent it from bringing about many striking cumulative results, in the manner postulated by Darwinians

I have wandered too far away from Mr Eltingham's book, but I must return to it to mention his remarkable experiments with the larva of a moth, *Odontoptera bidentata* Larvæ fed on ivy were offered to a lizard, and found extremely distasteful They were, although of cryptic coloration, nearly always rejected by the reptile Several larvæ were then transferred to apple, and after feeding on this

plant for a few days were again offered to the lizard, which ate them readily. Thus it is shown that a mere change of food plant may be of great importance in relation to destruction by natural enemies; furthermore, that some distasteful larvæ do not possess "warning" coloration, and again, that these cryptically colored larvæ were not recognized, after a few days, as objectionable. It would be interesting to repeat the experiment, having, if possible, ornamented the larvæ in some way so that they would be more easily recognized.

T. D. A. COCKERELL

UNIVERSITY OF COLORADO

Sewage Disposal. By LEONARD P. KINNICUTT, Director of the Department of Chemistry, Worcester Polytechnic Institute; C.-E. A. WINSLOW, Assistant Professor of Biology and Biologist in charge of the Sewage Experiment Station of the Massachusetts Institute of Technology, and R. WINTHROP PRATT, Chief Engineer of the Ohio State Board of Health, late director of Sanitary Engineering of the Republic of Cuba. New York, John Wiley & Sons. Price, $3.

This octavo book of 421 pages consists of a well-blended recital of American and European, especially English, experiences which have established the principal features now recognized in the science and art of sewage disposal. Almost without exception it is free of views that are either radical or so old-fashioned as to be regarded as superseded.

The joint authorship of this book has much to commend it and it will be noted that it includes in Professor Kinnicutt one of the foremost sanitary chemists in America, and one who has been fortunate enough to make numerous inspection trips to sanitary works in Europe, during the past thirty years. Professor Winslow, formerly of the Institute of Technology, in Boston, now of the College of the City of New York, has had unusual opportunities of studying the biology of this subject, particularly in connection with extensive experiments made at Boston. The practical side, from an engineering standpoint, has occupied the attention of Mr. Pratt for many years, first in Massachusetts and later in Ohio, with a valuable experience in Cuba.

The chemical and biological aspects of the book are more comprehensive and detailed than those of an engineering nature. Probably this is wise in a book of this size on a subject of such a wide scope as this one and which is undergoing such rapid changes in some of the more important aspects of engineering practise. Numerous references are given to details of results obtained from the findings of the Royal Commission on Sewage Disposal of Great Britain, as well as the results of tests and practical operations in America and abroad, especially in England. References are rather meager as to German investigations and experiences. To some extent the same is true of the results of current practise in the design and operation of disposal works in the United States other than in Massachusetts and Ohio.

After an interestingly stated introduction as to the sanitary demand for sewerage and sewage disposal, the book is divided into thirteen chapters, of which brief mention may be made to advantage as follows:

Chapter 1, pp. 1–20, deals with the composition of sewage in the terms of the analyst. Chapter 2, pp. 21–44, outlines the disposal of sewage by dilution. Chapter 3 gives many details as to the screening and straining of sewage, pp. 45–67.

The preliminary treatment of sewage by sedimentation, chemical precipitation and septic process occupies Chapters 4, 5 and 6, pp. 68–166. These chapters are unusually well-written, although they do not bring fully up to date very recent developments with the so-called "Imhoff" tanks, which have shown themselves to be a marked step in advance during the past year or two in practical operations in western Germany.

The expensive, bothersome and frequently unsuccessfully solved question of the disposal of sewage sludge is well outlined on pages 167 to 192.

Chapters 8 to 11, inclusive, on pages 193–274, contain a well-balanced statement of ex-

periences in this country and abroad as regards filtration in intermittent sand filters, contact beds and trickling filters.

The remaining chapters, pp. 375–409, contain first a full statement of the recent work done in this country in the sterilization or disinfection of sewage, with data as to the efficiency and cost, while the book is concluded with a brief summary of the main features of sewage analysis with particular reference to those tests of most benefit in practical operations.

The book is very attractively written and is well indexed There are 113 figures illustrative of the various distinctive features of the principal processes. The more one studies the book the more apparent it is that there has been a vast amount of study given to the compilation of a wide fund of information so as to embody it compactly for convenient reference The book is free to an unusual extent of statements to which exceptions will be taken by experienced sanitarians. The principal points on which there would be differences in opinion are in reference to the residual quantity of dissolved oxygen which would be found in a stream into which sewage has been discharged, and the disparaging reference to automatic controlling devices for the operation of contact beds.

Taking the book as a whole, it may be safely said that it will be of much assistance in the class-room in teaching this subject to students and especially to the public hygienist desiring to get a general insight into the subject in its broader phases, with ample opportunity to ascertain where the various results with different styles of plants have accomplished definitely recorded results.

GEO W. FULLER

The Practise and Theory of the Injector. By STRICKLAND L. KNEASS Third edition, revised and enlarged. New York and London, John Wiley and Sons. 175 pages, 53 illustrations and diagrams.

This book possesses the great merit of having been written by one who is a master of his subject. It is no ordinary compilation; it is the reflection of a life work. Its author for more than a quarter of a century has given serious attention to the problem of perfecting the injector. He has made it a part of his business to study the fundamental principles underlying its action, to conduct experiments which would supply data with which to embellish the theory, and to contribute to the working out of actual designs which from time to time have become the standards of a great manufacturing company, yet such is his modesty that nothing which is printed suggests his personal activity in the development of the instruments he describes. The book presents in logical order the fascinating story of the development of the steam injector, an instrument which serves to feed water to a steam boiler through the action of a jet of steam drawn from the boiler which is fed. In the language of the book, "'its mode of action, extraordinary in appearance, contrary to that which we are in the habit of seeing or supposing, is explained by the simplest laws of mechanics and has been foreseen and calculated in advance'" The book is interesting throughout because its story is well told. It deals with a subject which can not be freed from mathematical theory, in a manner which is sufficiently complete to satisfy the most fastidious lover of equations, and yet the work is so admirably arranged that no one who is interested in the subject is likely to find difficulty in reading it

The introductory chapter on the early history of the development of the injector, from which the lines quoted above were taken, is chiefly a story of the achievements of Henri Jacques Giffard, who as early as 1850 had succeeded in developing the principles underlying the design of the present-day instrument. The injector, as a device for feeding boilers, was introduced into England in 1859, and into this country by William Sellers and Company the following year. The story of a demonstration of its action in England by one who had received a sample instrument from France is graphically told as follows:

I set to work at once, and by good luck coupled up the correct pipes to their proper flanges, but

was a great deal bothered what to do with the overflow flange. After a few nights' work I got my Injector fixed and got up steam, and to some extent began clumsily experimenting as the pressure rose to 60 pounds, the full working pressure of the boiler. I had the Injector fixed over a tank fed by a ball tap and closed by the boiler. I turned steam on and was staggered by the rush of water into the tank from the overflow pipe, and thought something was wrong. However, I continued to turn the steam spindle, and the escape from the overflow sensibly diminished until I could turn no further. In the meantime the ball tap started running furiously into the tank, showing me that water was going somewhere, and I knew it could go nowhere else but into the boiler. I then began to operate with the four thread screw at the side, and found that it adjusted the water supply, and succeeded in getting the overflow "dry." I then opened the peep-holes opposite the space between the combining and the receiving nozzles, and saw the white steam passing from one to the other on its way to the boiler. I then ceased operations, and had a pipe of tobacco,

The second chapter deals with the development of the principle of automatic regulation, by the adoption of which the injector was made to adjust itself automatically to conditions imposed by changes in steam pressure. The evolution of the various devices, which have been employed in the accomplishment of this function, is well set forth. Following this are several chapters dealing with the elements of design underlying each of the more important details of the injector, such as the delivery tube, the combining tube and the steam nozzle. These chapters, while constituting the more technical portion of the volume, are nevertheless so clearly expressed that the reader emerges from them with interest undiminished. A chapter entitled "The Action of the Injector" presents an analysis of the action of the entire instrument with numerical examples. It constitutes a basis for the design of such instruments, and it supplies the means for determining what are the limiting factors under conditions that may be prescribed or assumed. The longest chapter in the book, entitled "Applications of the Injector" presents excellent descriptions of the different well-known types of injectors now obtainable, with some discussion as to their adaptability to the requirements of different service. Another chapter discusses methods of determining the size of an injector and methods of testing, and presents data derived from tests. A chapter on the requirements of modern railway practise deals chiefly with matters affecting repairs and renewals, and a final chapter discusses certain problems which arise in practise, in connection with the use of injectors in locomotive service.

At a single point only does it appear that the author slips and this is when he discusses a detail in locomotive practise rather than one affecting injector design or operation, and when a book, as a whole, is strong and true, it is perhaps ungracious in the reviewer to call attention to half a dozen lines which are in no way essential to the purpose of the book and which constitute, in fact, no more than an unguarded suggestion. There are other relations, however, in which the statement becomes one of some importance, and consequently it should not go unchallenged. Under the head of "Feeding Locomotive Boilers," the author advises that "in approaching a station at which a short stop is made, especially between long and fast runs, it is advantageous to stop the injector a short time before the station is reached, to permit a slight checking of the fire, and then, when the station is reached, to feed the boilers quickly with one, or even with both injectors if necessary, to prevent blowing off at the safety-valve." The practise here outlined is one which has been often suggested and sometimes practised. It is, however, objectionable from several points of view, and as a practise should not be tolerated. The water in a locomotive boiler when the throttle is closed is in a quiescent state. Feed water entering under these conditions is not as rapidly mixed with the water already in the boiler as it is when the throttle is open and the process of ebullition is active. As a consequence the feed entering the boiler while the locomotive is stopped at a station, being comparatively cool, settles in the lower portions of the boiler,

where it cools the metallic parts with which it has contact, and by so doing induces strains which complicate the problem of boiler maintenance Moreover, a locomotive which is thus filled is not in good condition for the start, notwithstanding the fact that the gauge may show full working pressure, for at the start there is imposed upon the boiler the double task of supplying steam and of raising to the maximum temperature of the boiler the water which was fed into it during the stop The result is that the boiler pressure soon falls, and considerable time is required in which to restore it

F M GOSS

UNIVERSITY OF ILLINOIS

SOIL PRODUCTIVITY

IN a discussion of the "Secular Maintenance of Soils" before the Geological Club of the University of Chicago on January 9, the undersigned expressed views as follows

That the era of soils began at an early but indeterminate period in the history of the earth, that the Proterozoic lands were probably mantled by soils and clothed with vegetation, that soils certainly prevailed on the land in the Paleozoic era, that sufficient soils and vegetation mantled the earth through all later eras to support the continuous evolution of land life, that the total eon of productive soils may be assigned a period of at least tens of millions of years, that therefore there must be some efficient natural process for the maintenance of soils

That the origin of the soil body lies chiefly in the granulation of rock; that soils are wasted at the surface by wind and wash, that wind and wash also distribute granules and mix soils and give to nearly all soils some of the essential soil constituents, that progressive granulation of rock adds soils below, that progressive solution removes soil matter from soils and from the rock beneath, that by these composite processes the body of the soil is at once enriched and impoverished; that so long as the *body* of the soil is maintained, any impoverished or anemic condition that may arise can be rectified; but if the *body* be lost, its restoration is tedious, laborious, or expensive

That the film-water that surrounds the granules of the soil when in a normal moist state is the specific soil water, that this is to be distinguished from the ground water that lies below the water-table, though these grade into one another, that the soil swells with the growth of the films in thickness, that there is an optimum of film-water when the soil is most swollen, that addition of water beyond the optimum destroys the surface tension of the films and leads to the shrinkage of the soils, the packing of the granules and to unproductivity,[1] that the solutions in the film-water are formed with facility because of the greatness of the surface contact relative to volume; that the concentrations of the solutions are controlled by the laws of equilibrium[2]

That the soil air is inversely proportional to the soil water approximately, that the soil air is to be distinguished from the earth's atmosphere, though grading into it and interchanging with it through diffusion and soil breathing, that, occupying the spaces between the film-coated granules of the soil, the soil air has great relative contact, that it acts at special advantage on both films and granules, that the union of minutely granulated earth, film-water under tension and interstitial air gives a combination of exceptional solvent and reactive power

That the soil is the home of minute life, plant and animal, that these intensify and modify the inorganic activities, that the forms of life are with little doubt more or less predatory and parasitic on one another, that these relations are probably in some cases pathogenic, and that these give rise to unsanitary states of the soil which affect its productivity, that progress is being made by Whitney and his associates in the discovery of toxic exudations that affect productivity, that plant societies are perhaps in part a result of mutually beneficial relations in respect to exudations and by-products, that the soil thus is little less than a world in itself, that its

[1] Cameron, *Journal Physical Chemistry*, 1910

[2] Cameron, *loc cit*

productivity is measured more by the efficiency of its complex of activities than by any mere measure of its inorganic constituents

That the capillary cycle, a sub-factor of the drainage cycle, is an important agency in maintaining the supply of potash and phosphorus in the soils, that the selective action of clays and of ferric oxides aid in a specific way the concentration of potash and phosphorus surfaceward, that at 592 localities in France analyses showed 68 per cent of the surface soils to be as high or higher in phosphoric acid than the subsoils, and 47 per cent. as high or higher in potassium than the subsoils, and similar facts are observed in America,[3] that the phosphate rocks in the sedimentary formations are largely *secondary concentrations*, that the formation of ferric and aluminic phosphates is a phase of concentrative action, that some of the phosphoric and potassic compounds are to be grouped with the silica and the aluminic and ferric oxides as the rock-elements that tend to stay in the soils, while the compounds of soda, lime and magnesia are more liable to go down to the sea, and the carbon and nitrogen to go off into the air, that these capillary and selective actions jointly are efficient factors in productivity, that Cameron's recent estimate[4] probably lies in the direction of the facts of the case, though confessedly only a tentative estimate based on elements not fully determined at present, viz, an annual drainage loss for the area of the United States of about 3,500,000 tons of potassium and 1,200,000 tons of phosphoric acid (PO_4), a possible crop-removal (reckoned at 1 ton per acre for the *entire* United States, carrying 1 per cent K, and 0 6 per cent PO_4) of 24,000,000 tons of K and 14,000,000 tons of PO_4, while, on the other hand, the capillary waters are carrying *toward* the surface 48,000,000 to 100,000,000 tons of K and 18,000,000 to 40,000,000 tons of PO_4.

That the plant-cycle cooperates with the capillary cycle in concentrating potash and phosphorus toward the surface by carrying these up into the plants whence they are deposited on the surface or in the soil, that the well-known rotation of legumes and cereals that enriches the soil in nitrogen may be supplemented by a *long-period rotation of trees and annuals* for the enrichment of the soil in potash and phosphorus

That the capillary cycle and the plant cycle conjointly contribute to a potash cycle and a phosphorus cycle by which these rise from the depths, pass into the plants, are shed as leaves, fruit and dead fiber on the surface—or pass through animals and are ultimately deposited on the surface—thence reenter the soil and are again taken up by plants, and so continue in the cycle until some intervening agency bears them out of it; that the length of this cycle is indeterminate and, in the absence of intervention, theoretically indefinite; that it is not, in the main, the *material substance* of the soil that is needed for food but *the energy* locked up in the grains, fruits, and so forth, by the anamorphic processes of the plants, that the real food comes chiefly from the sun and the material substance that temporarily embodies it is returnable to the soil indefinitely to be used again and again, that the really vital thing is the promotion of the cycle formed by plant anamorphism (solar energy going in) and animal katamorphism (solar energy coming out), that the contingencies of loss lie chiefly in the removal of the katamorphic products before they again enter into a new anamorphic process, contingencies that man emphasizes

That the SzeChuanese of West China, occupying a hilly sub-mountainous sandstone region whose area is less than that of Texas, a people numbering 68,724,800 according to the Chinese census, embracing more farmers probably than does the entire United States, have cultivated their soils continuously from an undetermined date before the beginning of the Christian era and quite without rock phosphates apparently, and yet have maintained a productivity exceeding, area for area, that of the virgin soils of America; that with little doubt this fertility can be maintained

[3] Bureau of Soils, U S Department of Agriculture.

[4] *Journal of Physical Chemistry*, 1910.

by the present mode of treatment until the country is base-leveled; that the SzeChuanese have thus demonstrated one mode of effective secular maintenance of the soil productivity, that their method is closely analogous to the natural method of the geologic ages; that a Chinese expert would criticize western practise as influenced unduly by prejudice respecting the use of the katamorphic products of human food-consumption.

That notwithstanding the loss due to this prejudice respecting the use of human katamorphic products, the soils of western nations generally show increases of productivity in the later years compared with the earlier, that, in particular, the data furnished by the Bureau of Statistics and the Bureau of Soils that the productivity of the soils of the United Kingdom, France, Belgium, Netherlands, Denmark, Germany, Austria, Hungary, Roumania and Russia show rather steady and notable increases in productivity for the last two or more decades that are covered by the statistics, that the lands most densely inhabited and most intensively cultivated, such as those of England, France, Germany and neighboring states, are more productive, unit for unit, than those of Russia, which are less densely occupied and less closely and persistently cultivated, that the old soils of Europe are more productive, unit for unit, than the newer soils of America; that in the United States the productivity of the last forty years shows general increase per acre, that the increase per acre in the older states, as the New York-New England group or the middle states, is more marked than in the southern or in the western groups, notwithstanding the larger proportion of virgin soil recently brought under cultivation in the last group; that while these and all similar statistics are subject to many qualifications in interpretation and application, they do not offer substantial grounds for an alarming forecast, applicable to an industrious and intelligent people willing to be guided either by oriental experience or by western scientific research.

UNIVERSITY OF CHICAGO

NOTES ON METEOROLOGY AND CLIMATOLOGY

THE effect of the recent construction of high buildings in New York City upon the United States Weather Bureau's records of wind velocity and direction for that city are discussed by Mr. E. S. Nichols, the local forecaster, in the October number of the *Monthly Weather Review*. Since the anemometer and the windvane were placed upon the American Surety Building at an altitude of 350 feet above the street in 1900, several new "sky-scrapers" have been erected in the immediate vicinity, vitiating to a greater or less extent the wind records since obtained. A comparison of the bureau's records with those of the New York Meteorological Observatory in Central Park, where the environment has not been greatly changed in forty years, shows that there has been a decrease of 16 per cent. in the hourly wind movement directly attributable to the recent construction. North winds have been affected the most, northeast and east have not been changed materially, while other directions have been considerably reduced. The number of days upon which gales have been recorded has decreased noticeably, and wind direction has been more or less deflected. Partly because of a desire to prevent the recurrence of such a condition in other cities, the bureau is gradually erecting appropriate buildings of its own in localities where future changes in the environment are not likely to affect the records obtained.

FROM an investigation of the relation between solar activity and terrestrial temperatures, Professor Humphreys has come to the conclusion that the decrease in the ultra-violet radiations received by the earth during the period of sun-spot maximum causes a similar decrease in the amount of ozone formed in the upper part of the earth's atmosphere. Moreover, since ozone allows the solar heat rays to penetrate it freely but absorbs most of the returning earth reflection, spot maxima indirectly produce diminished terrestrial temperatures. Abbot and Fowle had already concluded that spot maxima are accompanied by terrestrial temperature minima, and vice

versa, but had not recognized the significance of ozone in the sequence of events. The revival of scientific interest in ozone dates from 1904, when the late Professor Angstrom showed that a large amount of it existed in the upper atmosphere. As much may be gained from a further study, the chief of the Weather Bureau has urged the International Meteorological Committee to investigate the problem.

THE latest publication of the English Solar Physics Committee, "Southern Hemisphere Surface-air Circulation," was prepared by Dr. William J. S. Lockyer, secretary of the Solar Commission of the International Meteorological Committee. The work consists of a study of the mean monthly pressure amplitudes, the tracks of the cyclones and anticyclones and the meteorological records of several Antarctic expeditions. In an earlier memoir Dr. Lockyer pointed out the apparent similarity of the air movements over Australia, South Africa and South America, and suggested that anticyclones which crossed Australia were indications of a continuous state of things occurring in a belt encircling the earth. In the present memoir he shows the presence of such a belt in which movement is from west to east. The survey, which is an extensive one, doubtless will aid in the attempt to associate solar activity with the air movements of the southern hemisphere. Moreover, it also suggests that greater importance, from this point of view, must be attached to the meteorology of the polar regions than has hitherto been the case.

FROM a study of simultaneous records made at Corona, Colo., altitude 11,660 feet, and Denver, Colo., altitude 5,347 feet, distant in an air line about 38 miles, Professor A. J. Henry arrives at conclusions which briefly stated are as follows: (1) In general the temperature changes at high and low level stations are nearly synchronous, in point of time, and similarly directed. (2) Any abnormal course of the temperature between a mountain station and a near-by low-level station can generally be explained by considering the pressure distribution over the surrounding regions to a distance of at least 1,000 miles from the station. (3) An inversion of temperature between Corona and Denver occurs most frequently when the latter is under the influence of a Montana anticyclone while the former is affected by a cyclone to the west. (4) The high southwest and west winds occasionally observed on Pikes Peak and Corona indicate the early formation of a cyclone to the northwest or north. (5) In winter, mountain temperatures fall whenever a cyclone passes eastward across the mountains, or southeastward from Montana to Kansas. (6) The temporary presence of an anticyclone in the Great Basin affects the winds upon the mountains of central Colorado, giving high temperatures and fair weather. (7) The latter mountains cause a slight lowering of the pressure in an anticyclone as it passes over them.

ACCORDING to the Bulletin of the Mount Weather Observatory issued by the Weather Bureau October 31, 1910, during the three years in which regular free-air observations have been made the kite flights over 5,000 meters above sea-level number 31. Of these, three are over 7,000 meters, while in six of the flights the kites flew at a greater altitude above sea-level than has been attained elsewhere. The flight of 6,440 meters made April 5, 1910, at the Royal Aeronautical Observatory, Lindenberg, Germany, is the seventh highest above sea-level. In the opinion of Dr. William R. Blair, who has charge of the aerial work, the kite-flying apparatus has usually been the limiting factor at Mount Weather, and as this is gradually being improved, he expects that the kites will attain still greater heights. The upper air data are not only used by the forecasters in the central office in Washington, but it is hoped that when interpreted they will add to our knowledge of the atmosphere as a whole. Owing to the nearness of the ocean sounding balloons are not liberated on Mount Weather, but they have been sent up periodically from Indianapolis, Ind., Fort Omaha, Neb., and Huron, S. D. As these experiments have resulted in the acquirement of very desirable data, it is probable that they will be continued and perhaps extended during the present year.

A PRELIMINARY report of the investigation of the upper air in Java has recently been made by Dr. W van Bemmelen and Dr C Braak Aerological investigation at the Batavia observatory was begun under the auspices of the Dutch government in 1909 Because of the proximity of the sea, pilot balloons only were used at first, and with these a more thorough knowledge of the upper currents was obtained Later recording instruments were elevated by means of captive balloons and kites, the latter being used above the sea as well as above the land It was found that during the period September–May the general air-current had easterly components up to the greatest heights attained (10–15 kilometers), though occasionally the west monsoon appeared at the ground, its average height having been found to be 5 4 kilometers No antitrade wind aloft was found However, on one occasion when a balloon attained a height of 18 kilometers it encountered a westerly wind, similar to the strong westerly winds which were observed at heights of 10–20 kilometers on Professor Berson's East-African expedition. This phenomenon still awaits an explanation

THE newly created professorship in meteorology at the National University at Utrecht has been awarded to Dr E van Everdingen, who assumed the chair October 17. Considering the recent history of meteorology, the inaugural address, "The Third Dimension in Meteorology," was particularly appropriate In Dr Everdingen's estimation, the setting apart of a chair of meteorology indicated a recognition that meteorology was now worthy of a place among the established sciences

As a result of many requests from teachers, students and others interested in the subject, the Weather Bureau has published a second compilation of standard books dealing with meteorology and its several branches The list includes about 150 titles, the selections having been made by Mr C Fitzhugh Talman, librarian of the bureau As stated in the introduction, "the present compilation is the fruit of several years' experience in dealing with the literature of the subject, and will probably meet the requirements of the majority of American readers and students"

THE action of the management of the recent International Aviation Meet at Belmont Park in taking out insurance against loss due to inclement weather is one of the first instances of its kind in America The practise is a common one in Europe, however, especially so in England, where managers of most of the outdoor gatherings have long insured through Lloyd's against loss from wet weather. The premiums paid for the risks were relatively large at first, but of late there has been a tendency toward placing the practise upon a scientific basis, statistics having been gathered with that end in view, and in consequence the rates have been readjusted

SPECIAL ARTICLES

INTERPRETATIONS OF RESULTS NOTED IN EXPERIMENTS UPON CEREAL CROPPING METHODS AFTER SOIL STERILIZATION [1]

IT is not my intention at this time to give the details of extended experiments upon soil sterilization and its effects, nor to enter any special criticisms upon the work of other investigators I wish only to call attention to some facts, observations and conditions of the work centered about cereal cropping and experiments upon soils which may indicate that a new light may be thrown upon the conclusions to be drawn, with that light emanating from a different source than has usually been indicated by most experimenters.

Observations and Reflections.—The following features of cropping and experiments will be familiarly known to most of you.

1. New Lands, when first sown to wheat or other cereals, produce quite lavishly in seed of high quality and at slight effort on the part of the farmer. These new land yields, in this country, are quite commonly taken as the standard of what ought to be expected

[1] Read before the Society of Agronomy, Washington, D. C, November meeting, 1910

2 It is a common experience that as soon as a particular cereal crop has become general, and that usually follows in a very few years, a marked deterioration, both in yield and quality, sets in The crop, except in special years, and under rare exceptions of special farming, seldom again reaches the same high grade of yield and quality Indeed, the yield generally falls to the average for the country, above which it can be raised again only through exceptional methods, and, to the chagrin of many of our most able agricultural educators, no philosophy of cropping or land improvement seems to give the farmer the desired results with any regularity, year by year, for any long period of time The crop or variety once a favorite in a locality usually has a short life and finally gives place to a real change in agriculture, seldom, if ever, to regain its place.

3 Not many theories have been advanced to account for these results. The chemist and his followers have usually directed thought in the matter, and agriculturists, generally, have taken the chemist's dictum that marked changes have occurred in the balance of plant food relations of the soil, thus accounting for the rapid first deterioration of the crop through chemical losses noticed in the soil. Thus if a lack of proteid is found in the grain of wheat and a loss of nitrogen is observed in the soil, it has been reasoned, without foundation, I think, that the noticed chemical loss in the soil is necessarily the cause of the deficiency in the kernel When our chemical friends have, by their own analysis, discovered that there is, however, sufficient strength of soil solution regarding all known necessary chemical elements to support a crop on a particular field, the failure to reach crop quality has been quite uniformly attributed, by them and the rest of us, to slovenly methods of farming, poor physical texture of the soil, degenerated seed, etc.

Any other special theories which have been advanced in particular to account for the facts have all been strongly influenced by the recognised fact that soil can be impoverished, reduced in its chemical strength. The Whitney toxine theory would appear to be only a reflection of this troubled state of the chemical and physical mind, associated with a desire to show that a complex plant growing in the soil and air acts upon the soil after the manner of a bacterial culture in a test tube. That I may not be misunderstood, I may say that I believe that certain soils may be exhausted chemically by cropping methods, that I think it is wholly possible that the excrementia of plants under rather constant cropping may have an analogous effect upon the crop to that noted in bacterial cultures upon the substratum, but that after several years of careful trials upon wheat and flax, both under culture house conditions, and under carefully planned plot trials, I have been unable to find any point which would tend to substantiate the toxine theory Nevertheless, the contention of Mr. Whitney, that the soils of cereal regions are not particularly exhausted is, in my belief, much nearer to the truth than the contention of the chemists and others that the deteriorated yields and qualities of wheat and other cereals are due to chemical exhaustion, and especially to nitrogenous exhaustion; for neither the chemists' exhaustion theory nor the toxine theory can account, to my satisfaction, for the failure of virgin soils to produce the yields characteristic of that region when such cereal cropping was first introduced. It is a fact that such lands are quite as liable to give the crop characteristic of the old, so-called, worn-out lands, as do the older lands It is not the uniform failure of the particular crop which causes it to be dropped by a farming community, for it is evident that all of the lands of a community can not be so depleted. It is the general uncertainty of giving results, year by year, which results in abandoning or ceasing to expect a proper yield. It is evident from the foregoing considerations that there are constant interfering agencies at work in cereal cropping regions which have not as yet been properly taken into consideration, for, even under the best weather conditions possible, essentially the same weather conditions which in a new

land region give fine yields, often the crop fails to give both quantity and quality even under our best planned systems of rotation and of soil fertilization.

4 Experiments in soil sterilization applied to such old and supposedly deteriorated soils have uniformly given quite marked improvement in results. The results have been so uniformly good, whether done by steam or by chemical methods, that one or other practise has become general with the glass house gardeners and seedling plant producers They seem, long ago, to have realized what sterilization of soil has done for them, but experimenters upon field crops still look for explanation for such improvements.

5 Two very interesting explanations of such effects of sterilization, both based upon carefully planned and executed experiments, have lately been attempted; and, as my experiments cover essentially the same fields of effort, and, when published, will show almost exactly the same results but quite different conclusions, I may be pardoned, at this time, for outlining these three sets of experiments and the results, with some slight comment upon the conclusions:

Mr. A. D. Hall, of Rothamsted, England, in SCIENCE, September 16, 1910, reports upon experiments conducted at the Rothamsted farm.

Speaking of wheat, he says.

Approximately the crop becomes double if the soil has been first heated to a temperature of 70° to 100°, for two hours, while treatment for forty eight hours with the vapor of toluene, chloroform, etc, followed by a complete volatilization of the antiseptic, brings about an increase of thirty per cent., or so. Moreover, when the material so grown is analyzed, the plants are found to have taken very much larger quantities of nitrogen and other plant foods from the treated soil; hence, the increase of growth must be due to larger nutriment and not to mere stimulus.

The explanation, however, remained in doubt until it has been recently called up by Drs. Russell and Hutchinson, working in the Rothamsted Laboratory. In the first place, they found the soil, which had been put through the treatment, was chemically characterized by an exceptional accumulation of ammonia to an extent that would account for the increased fertility. At the same time it was found that the treatment did not effect complete sterilization

The question now remaining was, what had given this tremendous stimulus to the multiplication of the ammonia making bacteria? By various steps, which need not here be enumerated, the two investigators reached the conclusion that the cause was not to be sought in any stimulus supplied by the heating process, but that the normal soil contained some negative factor which limited the multiplication of the bacteria therein.

Examinations along these lines then showed that all soils contain unsuspected groups of large organisms, of the protozoa class, which feed upon living bacteria These are killed off by heating, or treatment by antiseptics, and on their removal, the bacteria, which partially escape the treatment, are now relieved from attack. . .

Curiously enough, one of the most striking of the larger organisms is amœba.

The authors, Messrs. Russell and Hutchinson, thus attempt to account for the greater wheat crop production of soil sterilization both through chemicals and through steaming, by a reverse application of the Metchnikoff theory. It would be unwise of me, not knowing all of their data or having access to the soil or the seed which they used, to enter a criticism, but from my own observations and work, I can not agree to any of the conclusions which are drawn in these paragraphs. So far as Mr. Hall has made plain in SCIENCE, they can only be matters of inference, and many conditions could enter, which would vitiate the necessity of assuming the detrimental rôle for the amœba. For example, the authors do not explain why their sterilization did not sterilize, and what happened when they did really sterilise the soil. In order to clarify the theory as proposed by Dr Hall, it would seem necessary to try real sterilization, both upon the amœba and the supposedly beneficial bacteria.

It is quite possible that the production of ammonia in soils by bacteria is a beneficial process, but I can not say wherein this theory would rest, if one should assume the presence of plenty of ammonia and plenty of ordinary nitrates in the soil. In such case, if the soil still failed to produce wheat, and proper ster-

ilization succeeded in making it produce wheat, their theory would seem to be without ground. My experiments in sterilization result in either good or bad wheat according to what I do to the seed planted therein, though there can not be any question but what in some soils increased amounts of ammonia through sterilization do have something to do with the results.

Experiment by Professor T. L. Lyon, of Cornell University, Bulletin 275, "Upon the Effect of Steam Sterilization on the Water-soluble Matter in Soils," attempts an explanation of the peculiarities of growth of the wheat plants upon soils after steam sterilization through differences in the soluble content of the soil resulting in differences in density of the soil solutions, etc. He also, however, seems to have great difficulty in accounting for some of the peculiar actions of the growing wheat plant upon such treated soils and solutions, especially in explaining what appears to be a really injurious effect upon the first growth from the seedlings, though finally followed by actual increase in crop.

In our experiments, we are able to explain most of these peculiarities of growth, noticed both in our cultures and those of Professor Lyon's admirably conducted trials, upon a biological relation of the wheat plant to certain actual disease-producing organisms and their growth relations to the crop plant, and to the various interreacting soil relations, which react both upon the crop plant and upon the disease producers.

In our experiments we find that both soil and seed may be, and usually are, infected by several very destructive wheat-destroying, parasitic fungi. Indeed, these are found to be apparently cosmopolitan in distribution with the wheat plant. They are especially transmitted in the seed internally, and, it seems quite certain, are sufficient in their influences to account for most of the causes of rapid first-crop deterioration, and for the difficulty which farmers have in introducing any sort of culture, which will again raise the standard of crop. Their exclusion, in so far as it is perfectly or imperfectly done, is sufficient to account for the anomalies indicated in soil sterilization experiments. However, in our experiments our results and conclusions have always been vitiated whenever these fungi were not eliminated.

I do not question that soil sterilization does change the bacterial content or that it does influence the soluble content of soils, but I am inclined to think that disease-infected seed and disease-infected soil will eventually be found to have much more to do with the irregularly corresponding conclusions, which have been drawn by various experimenters upon crop rotations, upon soil-fertilization experiments and upon soil-disinfection experiments than they have ever suspected. Indeed, I have but slight doubt that the whole theory of auto-intoxication (toxine theory) as applied to cropping plants, is virtually vitiated in its conclusions, because of a lack in eliminating the influences of pathogenic organisms in the experiments.

H. L. BOLLEY

AGRICULTURAL COLLEGE,
NORTH DAKOTA,
November 1, 1910

TERTIARY DEPOSITS OF NORTHEASTERN MEXICO

DURING the past two years, the geologic work under my direction in southwest Texas and northeast Mexico has resulted in the accumulation of a mass of information which materially adds to our knowledge of the Gulf Tertiaries. The fieldwork was carried on by Messrs. W. F. Cummins and W. Kennedy, assisted by Mr. J. M. Sands.

The first year's work by Professor Cummins was a general examination of the northeastern Mexico for artesian water. Following this, I had a careful section made of the Cretaceous and Tertiary deposits along the Rio Grande, and then traced the contact between the two systems southward into Mexico as far as this could be done within the scope permitted by our economic work. The widespread occurrence of the different phases of the Reynosa formation prevented direct connections of the exposures of the underlying deposits in some places, but we were able to

carry the Cretaceous-Tertiary parting with a fair degree of accuracy from the actual contact at the Arroyo del Caballero on the Rio Grande to a similar contact at Ramones, forty miles east of Monterey, and from Panalito on the Conchos River to the southern boundary of the state of Tamaulipas We hope to fill the gap between Ramones and Panalito before we finish

Numerous sections were made of the overlying Eocene to the eastward of this line of contact and good collections of fossils were made from various horizons in it, which prove that the substages recognized in Texas continue south as far as we found any deposits of this age We were able to map approximately the areal distribution of each of these.

The highly fossiliferous deposits on the Rio Grande which constitute the upper member of the Cretaceous of that region and which are known as the Escondido beds, only continue southward in this character for forty miles to a point southwest of Laguna de la Leche, where they are covered by much later deposits Where these later deposits end near the Salado river west of Rodriguez we find underlying them, in place of these fossiliferous beds, beds of blue shale without fossils, which have the same relation to the overlying Tertiary that the Escondido has through its whole extent These blue shales, which we call the Papagallos shales, are therefore considered to be the extension or equivalent of the Escondido and are found to extend south to the limit of our investigations To the south, these blue shales draw nearer and nearer to the coast until at their crossing of the Zarziza in southern Tamaulipas there is barely ten miles of Tertiary deposits between the outcrop of the shales and the waters of the gulf

On the Rio Grande and at several other points between that stream and the Pesqueria we found deposits of Midway age, as proved by its characteristic fossils, resting directly on the Cretaceous, but for the most part this basal contact is covered or obscured by the overlapping Carrizo sand The last of the Midway was seen at Ramones

When we again pick up the contact at Panalito on the Conchos River, we find both the Carrizo sands and Marine beds in contact with the blue shales of the Cretaceous, while a few miles down the river the Yegua overlaps both of these and is the substage in contact almost to the Soto la Marina. A few miles north of this river, the Yegua, Fayette and Frio are in turn covered by the San Fernando beds and beyond that point we found no further exposures of the Eocene

South of the Soto la Marina River the beds of the Eocene seem to be entirely wanting, if they were ever laid down Our drilling records as yet show no evidence of them, unless some part of the blue shale on which the San Fernandan rests be proved later to be of Eocene age No fossils have yet been found in this shale, but its general character and relations to overlying Tertiary as well as to the Escondido and to other known Cretaceous deposits seem to warrant its reference to the latter period

The San Fernando beds, which are regarded as Oligocene, were first observed at San Fernando on the Conchos or Presas River and have an extensive development to the south, entirely overlapping or replacing the Eocene deposits and resting directly upon the Cretaceous This formation, with its beds of nummulitic limestone and great numbers of cristellaria, carries an extensive and varied fauna and has a much greater development than previously observed It is succeeded by other beds of similar composition, but of distinctly later age, which in turn overlap it and reach the underlying Cretaceous shales

These later beds continue down the coast as far as Tecolutla They are well exposed at Tuxpam, where they have a highly characteristic fauna, including two very heavy oysters which are nearly round Both are of the same general shape, but one of them has on one valve four or five deep plications The echinoderms of these beds are especially noteworthy, there being probably eight species in our collection. The most abundant form is a *Clypeaster* which attains a diameter of

seven inches and which occurs in great numbers in the yellow sands around Tuxpam.

There are also casts of a large variety of other forms of bivalves and gasteropods, and as a whole the fauna is later than that of the San Fernando beds and is probably Miocene. We have called these the Tuxpam beds.

The evidence now before us indicates that the upper Tertiary deposits mark a gradually sinking coast line along the gulf border in Texas and Mexico which was arrested in the Tampico-Tuxpam region before it was further north. Thus while early Miocene deposits are on the surface almost at the present water's edge at Tampico and have only a small depth of later deposits overlying them, deposits of the upper Miocene are buried 2,300 feet on Galveston Island and are found in drilling at Saratoga seventy miles inland at a depth of over 1,000 feet.

E. T. Dumble

SOCIETIES AND ACADEMIES

THE AMERICAN PHILOSOPHICAL SOCIETY

In an address on modern physics before the American Philosophical Society, recently, Professor Ernest Fox Nichols, president of Dartmouth College, said in part:

"I shall try to review very briefly the principal ideas upon which modern physics rests and shall say something about where we think we have arrived in our search for knowledge. I need scarcely remind you that in the natural sciences as in more practical affairs, *how* we have arrived is as important as *where* we have arrived. I shall therefore spend some time in presenting detached fragments of the experimental evidence and inferences upon which certain conclusions are based, hoping in this way to illustrate some of the constructive methods of reasoning employed in research.

"The ideas which underlie all our thinking are space, time and inertia or mass. With space and time as a background, the physicist must pursue inertia and everything related to it, along every conceivable path. In this pursuit he comes upon four ultimate though related conceptions: matter, ether, electricity and energy.

It should be remembered that an important part of our present knowledge of matter, and nearly all that we know of ether and electricity, has been gained not immediately but by inference. In so many cases we see or know directly only the first and last link of a chain of events and must search by indirect means for the mechanism lying between.

"At bottom, I suppose, the ether, electricity, force, energy, molecule, atom, electron, are but the symbols of our groping thoughts, created by an inborn necessity of the human mind which strives to make all things reasonable. In this reasoning from things seen and tangible, to things unseen and intangible, the resources of mathematical analysis are applied to the mental images of the investigator, images often suggested to him by his knowledge of the behavior of material bodies. This process leads first to a working hypothesis, which is then tested in all its conceivable consequences, and any phenomena not already known which it requires for its fulfilment, are sought in the laboratory. By this slow advance a working hypothesis which has satisfied all the demands put upon it gradually becomes a theory which steadily gains in authority as more and more new lines of evidence converge upon it and confirm it.

"As we take up what we believe to be the relations of electricity to matter, we come in places upon slippery ground and the bases of our faith rest on recent foundations.

"At the outset we encounter one striking difference between electricity and matter. Every free charge of electricity exerts a force upon every other charge in the universe, just as every particle of matter exerts a force on every other particle of matter, however distant. But with matter the particles are invariably urged toward each other while electric charges may be either drawn together or forced apart depending on the kinds of charges. We have both positive and negative electricity but only one kind of matter. The bald statements of the laws of gravitation and electric force bear a strong resemblance to each other. The laws tell us how the forces *vary*, but reveal no hint of the machinery by which they *act*. Of the intimate association of electricity with matter we have learned much from careful study of the processes of electric conduction in solutions and gases."

The contributions to our knowledge gained from the recent discoveries of cathode rays, X-rays, spectroscopic studies and the amazing properties of radio-active substances were next discussed and in closing Dr. Nichols said:

"The electron has but a thousandth part of the inertia of the lightest known material atom, and this inertia it doubtless borrows from the kindly

ether and does not hold in its own right. Its behavior is that of an atom of negative electricity pure and simple Its form is spherical and not spheroidal Its size is probably less than one ten-million-millionth of an inch When revolving briskly enough in an orbit within the atom it gives us colored light of highest purity When violently jostling irregularly about it gives us white light, without it all light would be impossible

"We believe we have found electricity free from matter but never yet matter free from electricity Finally comes the suggestion that matter no less than life may be undergoing a slow but endless evolution Some of these things and many others have led physicists to suspect that if all electricity were removed from matter nothing would be left, that the material atom is an electrical structure and nothing more

"There are, however, many stubborn questions to which answers must somehow be found before the so called electron theory of matter can be accepted unreservedly As it stands it is at once a most brilliant and promising hypothesis but has not yet reached the full stature of a theory

Should it hold good the material atom with its revolving electrons becomes the epitome of the universe The architecture of the solar system and of the atom, the very great and the very small, reveals the same marvelous plan, the same exquisite workmanship The conservation of energy becomes an ethereal law and the ether the abiding place of the universal store of energy

"To end as we began, we have matter and electricity which some day we may know to be one, and ether and energy Of these we hope some time to build, in theory, a reasonable world to match the one we now so little understand

"When all the interrelations among matter, ether, electricity are separated out and quantitatively expressed, we believe our work will be complete.

"Such then is the confession of faith, the very far distant hope of the modern physicist"

November 1, 1910

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 687th meeting of the society was held on January 14, 1911, President Day in the chair Two papers were read:

Discrepancies among Recent Wave-length Determinations I. G PRIEST, of the Bureau of Standards.

The speaker, in introducing the subject, reviewed briefly the history of spectroscopic standards, stated that the accuracy at present desired is about 0 001Å, and gave a brief description of the "method of diameters"

In regard to the discrepancies among the results of Fabry and Buisson, Pfund and Eversheim,[1] the following conclusions were presented and supported by tabular data[2]

1 The difference $(F \& B)_{08} - P_{08}$ is not markedly systematic when the whole range of the spectrum covered is considered Considering the precision of the measures, the systematic difference that does appear is perhaps negligible

2 Throughout the range of the spectrum from 5,167Å to 6,495Å, inclusive, the difference $(F \& B)_{08} - P_{08}$ is sensibly systematic, the algebraic mean discrepancy being $+0\,0015$Å Out of the total of twelve differences to be considered in this range, only one is negative, viz, $-0\,001$Å for $\lambda = 5{,}167$Å, the limit of the range

3 Throughout the range of the spectrum from 4,282Å to 5,002Å, the difference $(F \& B)_{08} - P_{08}$ is not *markedly* systematic, although there is a slight predominance of negative values, the algebraic mean discrepancy being $-0\,00043$Å Out of the total of eleven differences to be considered, four are positive, five are negative and two are zero

4 Considering the whole range of the spectrum covered in common by the several investigators, the results of Eversheim appear to be systematically higher than those of Pfund and Fabry and Buisson by about 0 001Å.

5 *The differences, $(F \& B)_{08} - E_{08}$ and $P_{08} - E_{08}$ when grouped according to sign are also grouped in certain spectral regions as indicated in Table I In the differences $P_{08} - E_{08}$ the coincidence of the grouping according to sign and the grouping in spectral regions is pronounced and unmistakable. The spectral grouping of the positive and negative differences $(F \& B.)_{08} - E_{08}$ while less pronounced than for the differences $P_{08} - E_{08}$ is not consistent with this grouping, and the tendency of the groups in the system $(F \& B)_{08} - E_{08}$ to coincide in spectral position with groups of the same sign in the system $P_{08} - E_{08}$ is decided*

[2] Initials and subscripts refer to authors and year of publication See also *Phys. Rev*, 31, 602.

Table I[5]

Group	Limits of Group	Number of Lines in Group	Distribution of Differences According to Sign: +	0	−	Algebraic Average of Differences
	(F & B)$_{av}$ − E$_{av}$					
I	4,282 4,598	9	4	3	2	0 0000
II	4,603 5,083	16	1	1	14	−0 0022
III	5,110 5,456	10	5	3	2	+0 0010
IV	5,498 6,495	17	3	5	9	−0 0014
	P$_{av}$ − E$_{av}$					
I	4,282 4,494	5	5	0	0	+0 0016
II	4,860 5,002	5	0	0	5	−0 0020
III	5,167 5,456	4	3	0	1	+0 0022
IV	5,498 6,495	8	0	0	8	−0 0038

The large discrepancies existing between Eversheim's determinations in the helium, cadmium and mercury spectra[4] and the earlier results of Rayleigh, Michelson, and Fabry and Perot were mentioned

As conditions of apparent significance in connection with conclusions 2 and 3 above, the two following facts were emphasized

1 The line of division between the group of wave lengths considered in (2) and that considered in (3) is sensibly coincident with the green cadmium reference wave length

2 Fabry and Buisson's and Pfund's correction curves for "dispersion of phase" cross each other at about this same wave-length

As a tentative hypothesis to account for conclusion 4 above, the speaker suggested an insufficient approximation in computing In support of this hypothesis, he stated that he had recomputed from the published data, the results under II., p 836, Vol 30, *Ann der Physik* (1909), and obtained values systematically lower than the ones there published These recomputed results were obtained on a ten place computing machine and so involved no approximation in computation Computation by seven place logarithms gave results *systematically* high, while computation by eight place logs checked the machine results It happens that the errors of the seven place table are additive instead of compensating in this case, so that the error in the final result may amount to + 0 002Å There is a possibility of the approximate logarithmic computation introducing a *systematic* error owing to the fact that all wave-lengths are referred ultimately either to the green or red cadmium wave lengths as standards, and to the fact that the values of K (see p 835, Vol 30, *Ann der Phys*) nearly enough equal to fall at the same point in the log table may be expected to frequently occur As to the importance of this latter condition, nothing can be said without consulting the original data It seems possible, however, that this condition if it occurs often enough, in connection with the error due to approximation in log λ, may cause a discrepancy about large enough to account for the observed discrepancy between the results of Eversheim and the other investigators

[5] Data from same sources as mentioned in footnote 1

Ocean Currents and Barometric Highs and Lows
Dr W J Humphreys, of the United States Weather Bureau

In the first part of the paper the speaker dealt with the five barometric highs on the oceans which remain substantially fixed in position throughout the year though varying in intensity, three of which are in the southern, and two in the northern hemisphere In the second part of the paper the speaker discussed the Aleutian and the Icelandic regions of low barometric pressure

A brief review was given of the explanations advanced by past investigators to account for the existence and character of these regions of high and low barometric pressure, none of which appeared adequate to account for all of the observed facts

Lantern slides were exhibited showing the isobars, isotherms and ocean currents over the ocean areas, and the relation of these to the existing high and low-pressure areas was discussed at some length, the purpose of the paper being to show the physical reasons for the existence of these highs and lows and to explain why they are where they are actually observed to be (This paper will appear in full in an early number of the Bulletin of the U S Weather Bureau.)

THE APPOINTMENT AND TENURE OF UNIVERSITY PROFESSORS[1]

THE subject, appointment and tenure of university professors, divides itself naturally into two parts. With the question of appointment will be considered also that of promotion. The statements of fact given below are confined to the twenty-two universities which belong to this association, viz.: California, Catholic, Chicago, Clark, Columbia, Cornell, Harvard, Hopkins, Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, Pennsylvania, Princeton, Stanford, Virginia, Wisconsin and Yale.

FACTS AS TO APPOINTMENTS AND PROMOTIONS

The appointment and promotion of members to professorial rank, with the exception of associate professors at Catholic University, rest with the governing board. Instructors and men of lower ranks are at some institutions appointed by the senate, faculty or president. Thus at Columbia they are appointed by the faculty subject to confirmation by the board, and such confirmation is purely formal. The governing boards have different names in different institutions. In the endowed institutions the boards are usually called trustees, in the state universities, regents, but neither of these rules is invariable. At Harvard and Yale the governing boards are called corporations, at Missouri the governing board is one of curators, at Iowa a board

[1] Address delivered at the meeting of the Association of American Universities at the University of Virginia, Charlottesville, November 10–11, 1910.

of education, at Virginia the rector and visitors.

The important point with reference to appointments and promotions is not as to the nature of the organization which makes the appointment, but as to the representatives that make the recommendations to the board, for in most cases as long as these representatives have the confidence of their board, an appointment or promotion when recommended is made The functions of the board in this matter are primarily financial The creation of a chair rests to a large extent with the board, since whether or not it can be supported depends upon financial considerations If the recommendations made can be financed, they are likely to be accepted; but if not they may be rejected on this ground Also on other grounds a board may exercise its veto power But almost without exception the boards do not regard it as their function to take the initiative in appointments and promotions Such initiative they place with the educational officers

Occasionally the members of a board of trustees have dealt directly in the appointment of members of the instructional force This is true at the present time to some extent in one of the institutions of the twenty-two, but this situation is exceptional and even in this institution probably temporary Almost without exception, when an appointment has been authorized by the board, the recommendation of the president or some other representative or representatives of the faculty is decisive.

In seventeen of the twenty-two institutions of this association the recommendations as to appointments, promotions, and removals rest with the president, chancellor or provost of the institution. In this paper the term president will be used to comprise all three. Of these seventeen institutions, in three the recommendations can be made only after the concurrence of or consultation with other academic officers These are as follows

At Kansas the recommendations go to the governing board through the chancellor, but such recommendations must come jointly from him, the dean, and head of the department concerned, the chancellor having the veto power if he wishes.

At Cornell the "statutes require that the president shall consult with the heads of departments before making nominations in these departments"

At Stanford appointments and promotions, with reference to which the president has the initiative, must be submitted to an advisory board consisting of nine members of the rank of professor, and when the president submits his recommendations he must state whether or not they have the approval of the advisory board

A part of the advisory board is elected from specified groups of departments and others are elected at large, all elections being without nominations by secret ballot of the academic council The term of office is three years, and one third go out of office each year Every nomination, promotion or removal of the instructional force, large or small, goes before this board In connection with this matter it is to be said that Stanford has no deans, the president dealing with reference to each department through its executive head, who is annually appointed by the president with the approval of the advisory board.

The five institutions in which the recommendations to the board are not made by the president are as follows:

At the Catholic University of America appointments of professors are made by the board of trustees "after consultation with the academic senate and with the faculty of the school comprising the depart-

ment to which the appointment is to be made." Associate professors "may be appointed by the academic senate, after consultation with the faculty of the school to which the appointment is to be made." The academic senate consists of the rector as president, the vice rector, the general secretary, the presidents of the university colleges, the deans of the faculties and two professors from each faculty.

At Johns Hopkins appointments are made by the board upon the recommendation of the academic council. This council consists of the president and ten professors.

At Minnesota appointments are made upon the recommendation of the dean of the college concerned after consultation with the president. In this case the usual positions of the dean and president are reversed.

At Pennsylvania the faculties of the several schools make recommendations for appointment and promotion to the trustees and provost. In case the provost does not concur in a recommendation, he retains the right of veto, but as a matter of fact has in no case exercised it.

At Yale "nominations for positions in the faculty of any existing department except the graduate school shall come originally from the permanent officers or governing board of that department." The term department, as here used, is equivalent to school or college. The faculty of the school or college acts upon the recommendation of a committee of five professors appointed by the dean, two at least of which are from departments of study outside of the vacant professorship. This committee after conference with the president and dean presents its recommendations to the faculty of the school or college. The recommendation of the school or college is transmitted to the corporation. In the graduate school the nominating committee is appointed by the president rather than the dean.

Also at Harvard in the medical school the recommendations are made to the governing board by the full professors instead of by the president.

The procedure at Columbia is somewhat exceptional in the matter of appointments, in that recommendations to the trustees for men of professorial rank are by their own board of education. Since, however, the president presents the names and records of the persons proposed with his expression of opinion concerning them, the result is the same as if he made formal recommendation to the board, and therefore Columbia is included in this class of institutions.

In the case of the academic senate of the Catholic University, the academic council of Hopkins, the faculty of Yale, the president is a member, and at Yale he must be consulted by the faculty nominating committee, not only so, but "no decision of the faculty shall be valid which does not receive the concurrence of the president unless it shall be discussed and approved by the corporation."

Therefore it is clear that even in these five cases the president has much influence in the matter of appointments, etc. Since the president makes the recommendations to the governing board as to appointments, promotions and removals in the case of seventeen institutions and his recommendations are usually accepted, the point of paramount importance in connection with appointments and promotions is as to the manner in which the president exercises his authority. As we have already seen, in three institutions, the president is required to advise with a definite body of officers before acting. In one case the president has a definitely announced plan of taking

advice before making a nomination. Thus, in California, the president has "at his own option and by his own suggestion, called together a committee consisting of professors of five nearest related departments for conference as to the nomination of any one professor The nomination of assistant professors and instructors is made by the president after conference with the departments concerned"

In the great majority of cases, fourteen in number, so far as I have been able to ascertain, the president makes his recommendations without any definitely announced plan of conference but with a very definite method of securing advice

1 Usually where the university is organized into schools and colleges with deans or directors, the nominations of all officers in a school or college are made after close consultation with and the concurrence of the dean or director Indeed, in many institutions the dean or director is expected to take the initiative in going over the ground and getting the material ready to present to the president This is especially likely to be true of the professional schools, but in some institutions is true of all schools and colleges

2 The president frequently, and in the case of some institutions usually, consults directly with the professor serving as the executive head of the department, and he may also consult with other professors of the department This is especially likely to be true of the college of liberal arts or a college of arts and sciences, as, for instance, at Harvard and Michigan In this case the duties of the deans mainly concern the students This situation is historical, in former years the president of the modern university having had as his main or sole function the presidency of the college of liberal arts

In consequence of this situation, in many institutions, the relation of the president to the departments of the college or colleges of arts and sciences is more intimate than with reference to the departments of other colleges

3 The president may consult with both the deans and the professors of the department concerned, and not infrequently he may consult with the professors of allied departments

I think it may be said that in general the president in the exercise of his authority of nomination takes advantage of all available sources of information Any president who acted independently would probably have a brief tenure of office In short, it is the general rule for the president before making a recommendation to have the concurrence of the professors of the department concerned, the dean or director of the school or college interested, and frequently the professors of allied departments

Nevertheless, it does not follow that the president always follows the recommendations received While he would not nominate a man contrary to the wishes of interested officers, he may decline to make a nomination or promotion of a man recommended by a department In other words, he exercises the veto power In some cases the president instead of exercising the veto power transmits the recommendations of the department with the information that he does not concur in them The result is the same The presidents of this association report that under such circumstances the governing boards hold the president responsible and invariably refuse to make an appointment which has not his concurrence While the president must necessarily depend upon the sources of information mentioned with reference to professional attainment, another important factor in the success of a professor

and his fitness for work in an institution is the personality of the man in reference to energy, adaptability and other general qualities Concerning these points the president has a right to a judgment If a man does not in his opinion come up to the standards which he holds he may decline to make a nomination or recommendation for promotion urged by a department

Finally, after a department is once established, very exceptionally the president might take the initiative in the nomination of a man of professorial rank Such an action could only be justifiable in case the president does not have confidence in the department as it exists This situation is more likely to occur in institutions that are trying to raise their faculties to a higher standard, for instance from that of a college to a university basis, than in those institutions the departments of which are well established and on a somewhat permanent basis.

The extent to which the president personally participates in the councils leading to the nomination of a man depends largely upon the proposed rank of the man His participation is usually more intimate with reference to the nomination of men whose appointments are indeterminate—professors and associate professors, he is perhaps more likely to accept the judgment of others without close personal investigation in the case of the assistant professor who is appointed for a definite term, and a mistake in reference to which is not so serious a matter He usually accepts without question the recommendation of the department or a dean for instructors and lower ranks.

THE POWER OF THE PRESIDENT.

It is clear from the above statement of facts that the president of the university for the great majority of the institutions of this association occupies a very important place in the building up of the staff. The question therefore arises as to whether his authority should be curtailed. During the past half dozen years a number of papers[2] have appeared which have strongly urged this, not only with reference to appointment and removal, but in other directions The writers of some of these have gone so far as to state that the office of president should be abolished

With reference to the particular point under discussion—the appointment and promotion of the instructional staff—the only substitute for the exercise of the nominating power by the president which has come to my notice is that the faculty shall elect and dismiss the professors, this being subject merely to the veto of the trustees This proposal goes farther than is the practise of the Prussian universities There, the faculty nominates three members for a vacant professorship, from among whom the minister of education selects one, but in one case out of three during the last seventy years, according to President Pritchett,[3] the minister has gone altogether outside of this list The reason assigned for so doing was that the faculties are likely to be influenced by "personal considerations in their choice, not by considerations of the highest usefulness of the man to be chosen" The implication that if in America the office of president were abolished and his duties assigned to the faculty, the situation would be similar to

[2] This class of papers is illustrated by "Closer Relations between Faculties and Trustees," James P Munro, *Science*, Vol 22, 1905, pp. 848–855; "Externalism in American Universities," George M Stratton, *Atlantic Monthly*, Vol. 100, 1907, pp 512–519, "Academic Control," J. McKeen Cattell, SCIENCE, March 25, 1906; "Academic Aspects of Administration," Joseph Jastrow, *Popular Science Monthly*, Vol. LXXIII., October, 1908, pp 326–339

[3] Henry S Pritchett, *Atlantic Monthly*, Vol 96, p 296

that of Germany, is erroneous, since in Germany the minister of education to a large extent performs the functions that the president does in America Indeed, with reference to the appointment of professors it is clear that the power of the minister in Germany is quite as great as that of the president in America

The proposal to have the faculties make nominations of professors has a certain plausibility, and, as we have seen, is practised in four institutions, but the plan has not generally appealed to the governing boards, nor do I think it probable that it will in the future.

The fatal defect in the administration of a university by the faculty rather than by the educational executive officers is its extravagance. When an educational institution was small the faculty could do its administrative work But in large universities, in the consideration of educational policies, which are agreed should belong to the faculty, progress can only be made by sending a matter first to a faculty committee The committee spends much time in whipping the matter into shape It then goes to the appropriate faculty After consideration more or less prolonged, if favorably acted upon, it goes to a university faculty, academic senate, or academic council This body in turn goes over the subject and finally acts It must be admitted that this procedure is extremely expensive

While expensive, I am not arguing for a change University unity is more important than administrative efficiency; and in order to secure harmony in a university it is necessary that the faculty exercise authority with reference to educational policies While costly, it will be necessary to leave educational policies in the hands of the faculty

If all the questions of administration, including that of appointment, were to be handled by the faculty acting either as a committee of the whole or through its committees which in turn report to the faculty, the faculty would have much less time to devote to their main duties—instruction and investigation. This would be the result of "increasing the legislative and administrative responsibility of the faculty" as proposed by Munro.[4]

At this point there is a curious inconsistency in the position of many members of the faculty At the very same time that they are complaining of the extent of authority of the executive officers they are also complaining of the amount of committee work which is required of them. They state that even with the situation as it is so much committee work is required that they are unable to do satisfactorily their own work

These and other considerations have resulted in a tendency not in the direction of curtailing the power of the president in reference to appointment, but, on the contrary, for the governing boards to place that power in his hands and hold him responsible This is illustrated by Virginia, an institution which, after having lived nearly one hundred years without a president, has created that office; and the University of Toronto which was even more recently reorganized along American lines with a president having practically the same powers as in the United States

The only constructive suggestion which I have seen in reference to the president is to have the professors, rather than the governing boards, elect him and determine his powers.[5] While it is not probable that the

[4] "Closer Relations between Faculties and Trustees," James P. Munro, SCIENCE, Vol. 22, 1905, pp 848–855.

[5] George M Stratton, "Externalism in American Universities," *Atlantic Monthly*, Vol. 100, 1907, pp. 512–519.

governing boards will consider this proposal, if it were adopted, I suspect it would turn out that in order to secure efficiency of administration the president would exercise substantially the same powers that he now does; and this would be the case whether or not it was originally so planned. If an educational executive officer is essential, then he must have the powers which are necessary to give efficiency, and as a result of evolution these powers would probably not very greatly differ whether the officer were elected by the faculty or by the trustees. Whether the faculties would choose presidents more wisely than the trustees may well be doubted, and the exercise of the function would be very likely to introduce factional strife which might endanger the usefulness of the man selected.

In reference to the particular point under discussion—the appointment, promotion and removal of professors—it can not, I think, be charged that the president does not fully realize the seriousness of his responsibility; indeed, of all of his functions that of nomination to the faculty is the one through which he is able to make the largest impression upon the development of an institution. If he is sufficiently wise in using the information and recommendations of the deans and other officers as to be successful in this and a faculty of high grade is built up, the reputation and influence of the university will be a rising one.

It appears probable that if there is any formal development in the near future in reference to appointment, it will not be in the direction of taking away the nominating power from the president, but toward having the president exercise the power reposed in him, after consultation or concurrence with some other académic body, as in the case of the council at Hopkins and the advisory board at Stanford. In this connection the question arises as to whether or not it would be better for the more numerous institutions in which the president exercises this power without any regulation, but under well defined principles, to formulate them into rules. Upon this point there doubtless will be great difference of opinion.

If future development goes in the direction of formulating rules for the advice of the president in the exercise of his power of nomination, it seems to me that it would be advantageous for them to be along the lines of providing a changing body for each case. The great strength of this plan would be that the president would continue to consult all the interested parties; whereas, an academic council may be largely composed of men who do not know the facts at first hand. This point is illustrated by the self-imposed rule of the president of the University of California, who, when considering the appointment of a man of professorial rank, calls together a committee of the professors of the five nearest related departments for conference. But this very case illustrates the difficulty of the formulation of the principles of advice into rules. In some instances it might not be advisable to consult with so many departments as five, and in other cases more than that number.

Considering the whole situation, I think it would be well to announce as a fixed practise, where this is not already understood, that the president in the exercise of his authority of recommendation to the governing board as to appointments, promotions and removals, should do so only after consulting the executive officers of the school or college concerned, and in cases where he regarded it as advisable, the members of the department concerned, with the recognized right of consultation

upon the part of the members of such departments If this were done, the faculty, the governing board and the public would know that the president in the exercise of his powers of recommendation has had the advice of some responsible academic body, and the cry of "czardom," "tyranny," "the powers of academic life and death," in reference to the president, which in most cases is wholly without foundation, would be lessened

THE FACTS AS TO TENURE OF APPOINTMENT

In general, the appointments of professors are "during good behavior," or "at the pleasure of the board" In some institutions the appointments are of indefinite tenure, or permanent In all cases the meaning is the same, that the appointment is one for life to the age of retirement, provided the appointee is efficient

The only variations from the above are as follows At the Catholic University, professors may be appointed for an indefinite period, for a specified time, on probation, or to serve a temporary purpose At Clark professors are appointed first for a term of five years and if reappointed "at the pleasure of the board" At Columbia appointments to professorial rank are for three years, or at the pleasure of the board Other institutions make occasional appointments for a definite term

In general, the terms of appointment of associate professors are the same as for professors (Here are included the junior professors of Michigan) The exceptions are as follows· At Hopkins the associate professor for the first five years has an annual appointment, and thereafter on the professorial basis At Stanford associate professors are appointed for five years Some institutions do not have the rank of associate professor

Assistant professors are usually appointed for a definite period, often for three years, but sometimes a shorter or longer period The institutions varying from the three-year term are as follows California, one year, Catholic, period either indefinite or determinate, Chicago, four years, Columbia, one year (called junior professors), Cornell, five years, Harvard, five years; Hopkins (associates), one year, Kansas, annual for two years, thereafter permanent, Illinois, permanent, Iowa, permanent, Indiana, permanent, Minnesota, indefinite, Missouri, indefinite, Nebraska, permanent, Princeton, permanent, preceptors with the rank of assistant professor, for a specified term, Catholic and Hopkins do not have assistant professors

It is notable that with the exception of Princeton the institutions which at once or almost immediately make the appointments of assistant professors for a permanent or indefinite tenure are a group of state universities in adjacent states—Indiana, Iowa, Illinois, Missouri, Kansas, Nebraska and Minnesota For this geographic association I have no explanation to offer, but doubtless a sufficiently deep investigation would find one

While not properly included in the scope of this paper, for the purposes of comparison the tenure of instructors is also given For the most part instructors are appointed for a period of one year The exceptions are as follows: Chicago, three years, Cornell, after one or more year's experience, two years; Harvard, annually, or for a term of three years; Indiana, permanent; Minnesota, indefinite; Nebraska, permanent, Virginia, usually indefinite, but subject to termination at the instance of either party, Yale, one or two years.

From the above statement of facts it appears that the practise of the institutions belonging to the Association of American

Universities with reference to tenure of appointment is well crystallized. Appointments of professors and associate professors are practically permanent. While in several institutions assistant professors are appointed for an undetermined or permanent term, commonly they are appointed for a definite term, and there is a strong tendency to make it three years. For instance, in some institutions where the appointment in the past has been for a longer period, five years, it has been changed to three years, as recently at Yale. In other cases where the appointment has been for a briefer term than three years, it has been extended to three years.

I am not aware of any criticism as to the above principles concerning tenure of appointment. They seem satisfactory alike to the trustees and to the faculty. In making the appointment of assistant professor for a period of years greater than one it is recognized that the man is far enough along so that the question need not be raised each year as to his fitness to continue, but also in the majority of institutions it is recognized that after having had a reasonable time in which to "make good" the question should come up without embarrassment to the authorities as to whether or not he shall be reappointed. Also at this time the question of his promotion naturally arises.

PROFESSORS SHOULD BE EFFICIENT

The question now arises as to what should be done in the case of a man of professorial rank, whether full, associate or assistant, who is not efficient. Not infrequently papers with reference to this subject appear to assume that universities exist for the instructional force, that the main thing is to give that force a comfortable and happy time, an opportunity for a somewhat easy existence as a teacher, leisure for browsing through literature, and long vacations. I shall not consider the merits of this hypothesis, but shall say merely that I adhere to the ancient view that universities do not exist for the instructional force nor even for the administrative officers, which include the president, but that they do exist for the students and for the public. This view I suspect governing boards as representatives of the public will continue to insist upon.

If this view be accepted, it follows that the instructional force of a university, both young and old, must be efficient. Whether or not a man is retained in a faculty should depend upon his capacity to meet his duty to the institution. There is no possible excuse for retaining in the staff of a university an inefficient man. In rapidly growing institutions, among the older men, it often happens that there are those who have worn out their lives in their service, and who have fallen behind the standard. In justice these men can not be requested to resign or be summarily dismissed. If in any institution there are such men, they should be pensioned. But the right of efficient instruction by the students should be respected. And certainly the young men on the staff of a university can claim no exemption from the principle that they are to be judged by the efficiency of their service to the students and to the public. This means that they must be good teachers or good scholars, or both.

Strongly contrasting with the above view is that presented by Lawton,[6] who says in reference to the professor: "His position should be as secure as one on the Supreme Bench, unless senile decay, permanent mental or physical disease, or fatal moral

[6] William C. Lawton, "The Decay of Academic Courage," *Edu. Rev.*, Vol. 32, p. 402.

lapse makes clearly obligatory his enforced (if not voluntary) retirement by a court composed largely of his associates

And Stratton[7] says· "The faculty alone should normally have the power to dismiss its own members."

If the above views were accepted what chance would there be for a change in a chair occupied by an inefficient man? Can it be assumed even with any degree of plausibility that there would be one change per annum in the entire twenty-two institutions of this association?

Throughout history it has been the desire of the privileged classes to allow none but the members of the class itself to remove, reduce or punish its own members, and oftentimes these desires have been recognized But in modern times for the majority of civilized nations, such privileges have been taken from the nobility, they are not likely to be instituted for the class of professors in America

The responsibility of the governing board and the executive educational officers to the students and to the people is vastly greater than any obligation to the professor The funds for the disbursement of which they are responsible are trust funds which to the best of their ability should be expended to accomplish the purpose for which the funds are available, and this is true whether the money comes from the public treasury or from private sources. If a professor does not efficiently perform his work he should not be continued. For a given institution, if care has been exercised in the building up of the faculty the cases requiring so drastic action as request for resignation or removal will be only occasional

[7] George M. Stratton, "Externalism in American Universities," *Atlantic Monthly*, Vol. 100, 1907, pp. 512–519

In the great majority of cases when the right of change is exercised because of the inefficiency of a professor, it has made no difficulty or comment, indeed, has rather strengthened the confidence of the faculty and the public in the governing body. For my own part, it appears clear that the ultimate authority to ask the resignation of or to remove a professor must rest with the governing body under the advice of the officer or officers who make recommendations as to appointments and promotions The exercise of this authority should be clearly exceptional, but certainly it should be performed whenever a professor is clearly inefficient.

The only cases which have occasioned any serious discussion in reference to the tenure of professors have been those in which for some purpose, apparently not directly connected with the duties of a man or his good behavior, he has been dismissed For such extremely exceptional cases I would propose no rule Full responsibility must rest with the appointing authorities

If they exercise the power of removal arbitrarily, the public will hold them sternly accountable, and their institution will suffer, because good men will not be so likely to go to a university in which the power of removal has been exercised in an indefensible manner, or exercised in a manner in reference to which there is any doubt. The public will always give the professor the benefit of the doubt.

In some cases where an institution has had a fairly good defense for the removal of a man, it has suffered for years in consequence of so doing. The punishment of the offending university by public condemnation is the most effective protection for the professor against arbitrary or unjustifiable removal

CHARLES RICHARD VAN HISE

SCIENTIFIC NOTES AND NEWS

Dr. Henry Fairfield Osborn, president of the American Museum of Natural History, was made curator emeritus of the department of vertebrate paleontology at the last meeting of the executive committee.

Dr Samuel G. Dixon, professor of hygiene in the University of Pennsylvania, and Dr George Wharton Pepper, professor of law, have been elected trustees of the university.

Dr W K Rontgen, professor of physics at Munich, and Dr Ewald Hering, professor of physiology at Leipzig, have been appointed knights of the Prussian order pour le mérite Dr Gustav Retzius, formerly professor of anatomy at Stockholm, has been appointed a foreign knight of this order.

An international committee has been formed to celebrate the jubilee of Professor Gaston Darboux's connection with university education, the work he has done for mathematics, and his services as permanent secretary of the Paris Academy of Sciences. It is proposed to present Professor Darboux with a medal, reproducing his portrait, together with an address signed by the subscribers

On February 8, a portrait of Professor W Boyd Dawkins, F R S, will be publicly presented to the University of Manchester where he has been professor of geology

Professor H. Lorentz, of Leiden, has been elected a foreign member of the Paris Academy of Sciences to succeed Schiaparelli

The Chemical Society of France has elected, as we learn from *Nature*, the following foreign honorary members: A. v. Baeyer, Munich; Emil Fischer, Berlin; P Guye, Geneva; L Henry, Louvain, Belgium, O Istrati, Bucharest; A. Lieben, Vienna, Louguinine, St Petersburg, Raphael Meldola, London, Paternò, Rome, Sir Wm Ramsay, London, and Ira Remsen, Baltimore. The late Professor S. Cannizaro had also been nominated by the council, but his death prevented his nomination being confirmed by the general meeting of the society.

The Adams prize has been awarded by Cambridge University to Professor A. E. H. Love, F R S, formerly fellow of St John's College and now Sedleian professor of natural philosophy at Oxford, for his essay entitled "Some Problems of Geodynamics"

Dr. Karl Chun, professor of zoology at Leipzig, has been awarded the gold Cothenius medal of the Halle Academy of Sciences.

Dean H C. Cooley, of the University of Nebraska, Mr Bion J. Arnold, of Chicago, and Dr J A L Waddell, of Kansas City, have received the degree of doctor of engineering from the University of Nebraska

Dr Chas K Mills and Dr Wm G Spiller, of the neurological department of the University of Pennsylvania, have been elected foreign corresponding members of the Société de Neurologie of Paris

Miss Mary C Dickerson has been appointed curator of the department of woods and forestry and assistant curator in herpetology at the American Museum of Natural History

Dr. David J Davis, of the Memorial Institute for Infectious Diseases, of Chicago, has been appointed pathologist to St Luke's Hospital, Chicago

Dr Frank M Surface has resigned his position as associate biologist, at the Maine Experiment Station, in order to accept a position as biologist in the division of animal husbandry, in the Kentucky Agricultural Experiment Station at Lexington.

Mr A Imachi, of the Formosa Experiment Station, at Taihoku, spent the week of December 31 to January 9 with the Bureau of Plant Industry in Washington Mr. Imachi is on his way to Yucatan to study the sisal hemp industry

According to Reuter's Agency the British South Africa Company has decided upon the despatch of a special commission to investigate sleeping sickness in Rhodesia. The commission will consist of Dr. Aylmer May, principal medical officer of northern Rhodesia; Dr. A. Kinghorn, of the Liverpool School of Tropical Medicine; Dr. Leach, of the Northern Rhodesian Medical Service; Mr O. Sil-

verlock, entomologist, and Mr Jollyman, bacteriologist

It is stated in *Nature* that at a recent general meeting of the Liverpool Astronomical Society it was resolved to raise a special fund for the purpose of a memorial to the late Mr R C Johnson, whose long connection with the society, in which he filled the positions of secretary and president, and his services in the interests of astronomical science, suggest that some permanent recognition of his work should be made

A memorial in marble to the late Sir John Evans, the anthropologist, has been placed in the parish church of Abbot's Langley, Herts, where he lived for sixty years

According to information received from Timbuctoo the remains of Alexander Gordon Laing, the African traveler, who was murdered in 1826 while exploring the course of the Niger, have been discovered at Saebb, some 50 kilometers north of Timbuctoo. The discovery was made by M Bonnel de Mézières, who had been commissioned by the governor of the French Upper Senegal and Niger Colony to proceed to Taudeni, some 300 miles north of Timbuctoo, in order to examine the salt mines of the district

Professor L. P. Kinnicutt, director of the department of chemistry in the Worcester Polytechnic Institute, well-known for his important contributions to sanitary chemistry and sewage disposal, died on February 6, aged fifty-six years

Dr Edward Gamaliel Janeway, professor of medicine and dean of the University and Bellevue Hospital Medical College, one of the leading physicians of the country, died on February 10, aged sixty-nine years

Dr Willibald A Nagel, professor of physiology at Rostock, has died at the age of forty years

M E A Léveillé, the French entomologist, has died at the age of seventy years

Professor Eduard Hagenbach-Bischoff, formerly professor of physics at Bâle, has died at the age of seventy-eight years.

Foreign exchanges announce the deaths of three astronomers M Gustav Leveau, known for his work in celestial mechanics and for more than fifty years an officer of the Paris Observatory, M Rozé, astronomical lecturer at the École Polytechnique, Paris, and Dr F. W Hermann Leppig, astronomer in the Leipzig Observatory

The Wabash College Botanical Society will this year send a representative to the Woods Hole Biological Laboratory to occupy a table which they will support

UNIVERSITY AND EDUCATIONAL NEWS

Dr and Mrs Robert W Long, of Indianapolis, have given $200,000 in real estate to the medical department of Indiana State University

By the will of Mrs Emily H Moir, of New York City, Barnard College received $10,000 Harvard University, Princeton University, Lincoln University and Howard University receive shares of the residuary estate

Illinois College, at Jacksonville, Ill, received recently $5,000 from Mr Edward F. Goltra, of St Louis This contribution is towards a new endowment of $150,000 which the college is raising Mr Andrew Carnegie has contributed one half of the amount, friends and alumni have thus far contributed about $65,000

Plans have been proposed to unite the University of Pennsylvania with the Pennsylvania State College and to make the relations between the university and the state more intimate

The sum of £25,000 required for the purchase of the site for new chemical laboratories at University College, London, has been completed by a gift of £4,500 from Mr Ralph C. Forster The total sum required for the purchase of the site and the erection of the laboratories was £70,000.

Dr. C. H. Neilson, professor of physiological chemistry in St Louis University School of Medicine has been made professor of medicine and director of the department. The chair in medicine has been put on a salary basis Dr. Neilson is an A B. from Ohio Wes-

leyan University, received his Ph.D. in physiology at Chicago in 1902 and his M.D. from Rush Medical College in 1905. Before going to St. Louis he was instructor in physiology in the University of Chicago, and at the Marine Biological Laboratory at Woods Hole.

MRS. MARGRETE BOSE has been appointed professor of chemistry in the University of La Plata. Her husband, Dr. E. Bose, is professor of physics in the university.

MR. JAMES LEES, of the University of Bristol, has been appointed lecturer in engineering in the South African College, Cape Town.

DR. FRANZ HOFMANN, professor of physiology at Innsbruck, has been called to the German University of Prague to succeed Professor Gad.

DISCUSSION AND CORRESPONDENCE

LABORATORY TABLES

TO THE EDITOR OF SCIENCE: Several months ago I read with interest in SCIENCE Professor Augustus H. Gill's suggestions for chemical laboratory furniture and fittings. Among other things he discusses various kinds of materials and surfaces for table tops. It occurs to me that it may be of sufficient interest to warrant calling attention to still another kind of surface for laboratory tables.

In our testing laboratory at The York Manufacturing Company we have tables with tops of ordinary wood. On this there are placed sheets or slabs of heavy asbestos board, one fourth inch thick. These are fastened in place by a few small brads driven around the edge. All around the outer edge of the table there is a narrow strip of wood of the same thickness as the asbestos board, making a permanent border. This, as a matter of course, is nailed in place. It prevents the edges of the asbestos from becoming frayed out. The advantages of this asbestos surface are almost self evident. Flasks and beakers containing hot water or solutions can be stood upon it without fear of their cracking. There is also little risk of breaking glassware by setting it down a little too hard, as is often the case on slate or stone or even wood, where particles of grit may happen to be. And of course the resistance of the asbestos to fire and heat is too well known to need any comment. There is the further advantage that when the asbestos slab becomes old and worn it is easily replaced without in any way disturbing the table, thus making the latter practically new.

We have found this plan highly satisfactory and pass on the suggestion for any who may desire to try it. It is quite possible that it is an old device after all.

C. H. EHRENFELD

YORK, PA.

A FORMULA FOR OPTICAL INSTRUMENTS

IN many surveying and optical instruments a ray of light is reflected by a pair of plane mirrors. And if ϕ be the angle between said mirrors, and the entering light ray lies in the plane commonly perpendicular to them, then, of course, the doubly reflected ray must cross its original path at the angle 2ϕ. And, although the ray sway from side to side, so long as it preserves its parallel position to this commonly perpendicular plane, so long also is the crossing angle still 2ϕ.

But now, should the entering ray be deflected at a variable angle θ to this commonly perpendicular plane, then the question arises as to the resultant effect upon the crossing angle, a problem that constantly arises in practise, and yet one, I believe, that the text-books leave unanswered.

The single solution is as follows: letting ϕ be the angle between the two mirrors, and θ be the independent variable angle that the entering light ray makes with the plane commonly perpendicular to the said mirrors, while δ is the crossing angle desired. Then,

$$(\cos\theta)\ (\sin\phi) = \sin\tfrac{1}{2}\delta,$$

a very simple formula, that can be easily demonstrated by elementary trigonometry.

In the special cases where the entering ray is normally inclined to the commonly perpendicular plane, and it be asked what errors may be produced by changes in the direction of that ray? we should simply determine, first, the angle ϕ between the two mirrors, and

secondly, the angle θ that the ray was designed to have with the commonly perpendicular plane, when the above formula will prove itself, by giving us the correct bend δ in the ray that the instrument was designed to produce. Whereupon any error on deflection in the entering ray either does or does not make a new angle θ' with the commonly perpendicular plane, giving us, therefore, by the above formula the new value of δ

UNIVERSITY OF PITTSBURGH

THE INSUFFICIENCY OF DATA ON ENVIRONMENT GIVEN IN PAPERS DESCRIBING DEEP-SEA AND OTHER MARINE ORGANISMS

TO THE EDITOR OF SCIENCE: In examining a number of recently published papers on corals, foraminifera and other marine animals, especially for the purpose of ascertaining the temperature conditions under which the organisms live, I have been particularly impressed by the fact that very rarely are any definite data given on the temperature of the waters from which they were taken. As it is a generally known biological fact that temperature is one of the most influential factors in determining geographic distribution, it is highly important that precise information on this subject should be available. In fact, the data on the physical conditions under which an organism was collected should always be presented as fully as possible. Depth, temperature, nature of the bottom, and relations to marine currents, are important factors. As so many zoologists are engaged on the description of marine faunas, and as it is more or less habitual to give very meager data on the conditions under which the organisms described live, this appeal for more detailed information is made to the body of investigators through the columns of SCIENCE.

T. WAYLAND VAUGHAN

SCIENTIFIC BOOKS

The Age of Mammals in Europe, Asia and North America By HENRY FAIRFIELD OSBORN. Illustrated. New York, The Macmillan Co. 1910.

Students of paleontology have awaited impatiently the past few years a promised work on extinct mammals by Professor Osborn. In his "Age of Mammals," as it has recently appeared, expectations have been more than realized For more than a century, beginning with the classic researches of Cuvier, our knowledge of extinct vertebrates has been increasingly widened, and of no group so greatly as of the mammals. In North and South America, throughout Europe, in India, and more recently in Africa, discoveries have followed discoveries so rapidly that all but the expert have nearly given up in despair the attempt to follow and understand. And it is superfluous to say that in no part of the world has the progress of our knowledge been so rapid as in North America. Those famous pioneers in American paleontology, Leidy, Cope and Marsh, followed soon by Scott and Osborn, and later by Wortman, Hatcher, Matthew, Merriam, Sinclair, Gidley, Peterson, Douglass, Loomis, as well as others whose names may be omitted here without invidiousness, have contributed abundantly and meritoriously to our knowledge of the history of mammalian life in North America

But, for some years it has been growing more and more evident that it was time that an inventory should be made of what we know. And this has now been done ably by Professor Osborn in this voluminous work of more than six hundred pages. That there is no place in the world where such a work could be written as the American Museum of New York City, with its extensive collections, and various experts in paleontology, especially Dr. Matthew, for aid and advice, vertebrate paleontologists know full well. That there is no one who could treat the subject more broadly and comprehensively than Professor Osborn will, also, be as readily admitted. Indeed there are few who are competent to criticize expertly the work as a whole, as the reviewer is painfully conscious, since he knows that he is not one of them. Vertebrate paleontology has advanced with such enormous strides within the scientific career of the present writer even, that it is no longer possible for

any one to be expert in more than one of its half dozen branches. But the writer does appreciate the merits of the work, since it will relieve him, in large part, as also many others, of the almost insurmountable difficulties he has encountered in attempting to keep abreast of the discoveries in mammalian paleontology.

In brief, the work deals with extinct faunas, rather than with the evolution of mammals, with "time and place" rather than with "descent", as the author says, it is "a study of the sources or birthplaces of the several kinds of mammals, of their competitions, migrations, and extinctions, and of the time and places of the occurrence of these great events in the world's history." As such, after the introduction, of which more later, it deals with the faunas of each great division, and its minor subdivisions, so far as possible, of the Cenozoic, geologically, geographically, environmentally and faunistically The author makes use of whatever available assistance is afforded by other branches of paleontology in his paleogeographic and climatic discussions, though not always with the same expertness that he shows in his more special field of research, the mammals, as for instance, the statement on page 106 that *Helagras* is the oldest known American serpent. Marsh years ago described the serpent *Coniophis* from the Lance beds, and the present writer can confirm his determination, and he also objects to calling *Champsosaurus* either aquatic or a lizard But the few such errors that the writer has observed are trivial, and it would be supererogatory to search for others

To give even a résumé of the work would be beyond the limits of this article Perhaps no part, other than the introductory chapter, will be of more general interest than that dealing with the Pleistocene, and especially that with man in his faunal and time relations. The writer is one who still believes, notwithstanding the objections raised by geologists and anthropologists, that there is paleontological evidence of man's contemporaneity in North America with some, at least, of the extinct mammals, and he finds of interest the summary of such evidence.

By the aid of sections, maps and photographs every known horizon of the North American Cenozoic yielding vertebrate fossils is located and defined, and correlated, so far as possible, with the horizons of other lands For the American deposits and faunas, and to a very large extent for those of other lands, the data of this work have been brought together from original sources, and the writer has sufficient acquaintance with the literature to perceive that very few indeed have been omitted or overlooked The numerous figures of skeletons, and photographs of restorations chiefly from the able brush of C R Knight, will especially commend the work to the general reader. Many of these figures have become familiar to students within recent years in special works and in texts They are here brought together and numerous others added

Not the least useful part of the work to the zoologist is the summary of the classification of the Mammalia in the appendix, with a list of the known genera, their range and distribution That it will be accepted immediately by zoologists in its entirety is hardly probable The writer for one, as a student of the extinct reptiles, demurs at the unreserved location of the Multituberculata among the Marsupialia, notwithstanding the apparently convincing discoveries of Gidley *Tritylodon* stands, confessedly, somewhere near the dividing line between the Reptilia and Mammalia, and the relationships between *Tritylodon* and the Multituberculata seem so clear that one can not accept the necessary conclusion that the reptiles evolved directly into marsupials That some or all of the Multituberculata will some time be proved to be oviparous the writer firmly believes, and there are others who believe so with him. The author accepts not less than thirty-four orders of Placentals, arranged under four chief groups, the Unguiculata, Ungulata, Primates and Cetacea. We need to add but three or four more "cohorts" of equivalent rank—and the author may rest assured that some of his zealous colleagues will promptly do so—and we again have essentially the older classification under new names. There is a similar

tendency in all branches of natural history, and the writer deplores it. Is it not just as well to call these chief groups orders with as little disturbance as possible to existing plans of classification? For, after all, it seems to be merely a question of names. However, classification of organisms is an art that passes understanding, and no one knows where it will end, possibly when all the species have been raised to genera and all the genera to families, and families to orders, etc.

Perhaps the most widely useful part of the work is reserved for the conclusion of this review—the introductory chapter. In this the author brings together in a readable way the underlying principles of paleontology, with especial reference to mammals, but also widely applicable, not only to all branches of paleontology, but to all natural history as well. The philosophy of structure, correlation, range, environment, the laws of evolution as applying to mammals in general and in detail, are among the subjects treated. Not all is discussed that might have been, not all the conclusions are beyond controversy, but, withal, it is the best summary of the guiding principles of paleontological research the writer has seen.

The writer can not recommend the work as one suitable to slip into one's grip for literary recreation on a vacational outing—it is a little heavy and forbidding in places. As a work of reference for the geologist and naturalist it is indispensable, and it will be a working tool for the student of extinct mammals. Perhaps, with the publication of this work there will no longer be an excuse for the further display of the dense ignorance concerning extinct forms that characterizes the most of our text-books in zoology—at least let us hope so!

In conclusion it may be said that this inventory of extinct mammals has been well done, the way is again cleared for a further rapid expansion in our knowledge of this class of vertebrates. And the author is to be commended and congratulated on the opportunities he has aided in opening up.

S. W. Williston

Catalogue of the Nearctic Hemiptera-Heteroptera. By Nathan Banks. Philadelphia, Pa., American Entomological Society. 1910.

This catalogue covers the entire group of Heteroptera for the Arctic region, and in this respect is of much greater service to the American student than the general catalogue of Kirkaldy which includes only a few of the families represented in this region. The work is rather a presentation of the existing knowledge than an attempt to rearrange the grouping or to introduce radical changes in the generally accepted nomenclature. The list covers 1,268 species and is particularly serviceable in certain families which have not been treated in recent years. Such a catalogue has been much needed, as the only work of a similar character, the list by Dr. Uhler, published over twenty years ago, is long since out of date. The paper shows some defects in proof reading, as for instance, the misspelling of *Macrovelia* and *Zicrona*, but on the whole it seems to be quite free from serious error. We can certainly share with the author the hope "that this catalogue will encourage entomologists to devote more time to this order, so that our forms will be better known to us."

Herbert Osborn

The Relation between Chemical Constitution and some Physical Properties. By Samuel Smiles, D.Sc., New York, Longmans, Green and Co. 1910.

The study of the relations between the chemical constitution and the physical properties of substances has interested chemists and physicists for a greater period of time than has the study of any other branch of chemistry which possesses more or less general interest at present. For this reason, the volume under review should exert a wider appeal than any which have appeared in the series of "Text-books of Physical Chemistry" edited by Sir William Ramsay, of which it forms a part. As part of a physical chemistry series it will appeal to physical and inorganic chemists, and it will also appeal to organic chemists, since as stated by Professor Smiles

in the preface, it has been written "from the standpoint of organic chemistry"

The subject matter is discussed under the following headings. Mechanical Properties, under which are treated Capillarity, Viscosity and Volume Relations, Thermal Properties, including Specific Heat, Fusibility and Boiling Point, Optical Properties, including Refractive and Dispersive Power, Absorption of Light, Fluorescence and Magnetic Rotatory Power, and Electric Property, including a short chapter on Anomalous Electric Absorption

In an introductory chapter, the development of the study of the physical properties is traced and the gradual increase in importance of these properties as aids in determining chemical constitution is clearly brought out. The concluding statement of this chapter that in determining chemical constitution "evidence drawn from physical properties should be regarded as subordinate to chemical evidence" will be concurred in by most chemists. In the sections dealing with the Mechanical and Thermal Properties, an unsatisfactory impression is obtained at times with regard to the scope of the theoretical treatment as well as the application to the experimental data On the other hand, in fairness to the author, it must be said that with the space at his disposal a more satisfactory treatment of these subjects is scarcely possible The same criticism does not apply to the chapters in which the optical properties are discussed, as here the treatment is clear and complete, especially in describing the relations which have been deduced between absorption and chemical constitution The additive and constitutive effects exerted by the atoms and groups of a molecule upon each property are carefully distinguished throughout and illustrated by concrete examples

The concluding chapter considers the present status of the subject and the most fruitful lines for further investigations In the opinion of the author, the study of the optical properties, including absorption and refraction, offer the greatest promise, but further advance along these lines depends upon a satisfactory theory of valence This, it is pointed out, is the most important problem awaiting solution from the chemist, and "the electronic theory seems to be the only means by which there is any prospect of attaining further knowledge of the nature of valence"

K. G FALK

Chemische Krystallographie By P VON GROTH Leipzig, Wilhelm Engelmann. 1910. Vol 3 Pp iv + 804, 648 figures; 8vo, cloth, 30 Marks (Volume IV is in preparation)

In 1904 Professor P von Groth, of the University of Munich, published his "Einleitung zur Chemischen Krystallographie," and followed it two years later with the first volume In 1908 the second volume of the "Chemische Krystallographie" was issued These volumes have all been reviewed in SCIENCE[1]

Groth's "Chemische Krystallographie" is a work of monumental proportions, and is to include the crystallographic data of all substances which have been described at the time of the publication of the individual volumes Inorganic compounds were discussed in volumes I and II The third and fourth volumes are to be devoted to organic compounds. In volume III, which has just been published, crystallographic data are given for the aliphatic carbon compounds, hydrobenzol derivatives and terpenes The method of treatment in this volume is the same as in the others, according to which all substances having a similar chemical composition are placed together and their descriptions prefaced by a discussion of the work done on the group. These discussions are suggestive as well as critical in character and make the work of much more value than a mere compilation of chemical crystallographic data could be. This volume, as well as volume IV, which it is hoped will be published before long, ought to prove of especial value to organic chemists.

[1] Vol XXV., 143–144; Vol XXVIII, 343

DO FERNS HYBRIDIZE?

IN a paper entitled "Physiological Aspects of Fertilization and Hybridization in Ferns,"[1] Dr. W. D. Hoyt gives considerable space to the evidence heretofore brought forward to prove hybridity among ferns. After considering the evidence under three headings, viz., (*a*) characters of the mature sporophyte, (*b*) experiments in which prothallia of different species have been grown together and some of the resulting plants have been considered intermediate, (*c*) experiments in which sperms of one species have been presented to eggs of another species, and their behavior watched, he concludes that the affirmative evidence is entirely insufficient, and that the only evidence which is worthy of consideration is negative. He also adduces what he considers additional negative evidence based on his study of the behavior of the gametes of certain ferns with which he worked.

Dr. Hoyt's paper deserves consideration for its physiological features. His experiments and observations as to the behavior of the sperms and the fusion of the gametes are extremely interesting. Unfortunately, however, the paper does not deserve serious consideration with respect to his conclusions regarding the evidence as classified under the first two headings. His conclusions on these points carry no weight whatever, because they are not based on a first-hand knowledge of the facts concerned.

For example, in order to be sure of the identity of the common ferns with which he worked, such as *Dryopteris Thelypteris*, he felt obliged to send his material to Mr. W. R. Maxon for identification. What weight then can his opinion carry with regard to what forms constitute reasonable variations of these common species and what forms are so different as to deserve a specific if not a hybrid rank? Dr. Hoyt's work with fern hybrids suggests the story which is told of a certain (or rather uncertain) investigator of the embryology of a species of *Pinus* who did not know the tree in life. Moreover, when Dr. Hoyt was beginning his study of this particular problem at the New York Botanical Garden, he did not even care to examine ample material of nearly all the reputed hybrids of *Dryopteris*, although he was offered every opportunity to do this. Apparently his mind was already made up on this point. He wished only to see the experimental plants which Miss Slosson produced by planting in pairs unisexual portions of the prothallia of *Dryopteris cristata* (L.) Gray and *D. marginalis* (L.) Gray, and *Asplenium platyneuron* (L.) Oakes and *Camptosorus rhizophyllus* (L.) Link, respectively. The fact that these experimentally produced plants are identical with the wild plants described as the hybrids of these pairs of species, Dr. Hoyt explains easily by suggesting that all may be mere variations. If he had known well the parent species and the reputed hybrids, he could not have made such a suggestion. Either there are hybrids in *Dryopteris*, et al., or else there are a considerable number of undescribed new species.

The third class of evidence is the only kind of which Dr. Hoyt has any adequate knowledge, and even here his unfamiliarity with the wild plants has reduced to a vanishing point the negative value of that which he presents. Thus he cites as the main evidence which he offers to disprove hybridity among ferns, the fact that he was unable to cause fusion between the gametes of two species which no one has ever suspected from field study to be in the habit of crossing, *i. e.*, *Dryopteris Thelypteris* (L.) Gray and *Dryopteris noveboracensis* (L.) Gray. Sixty-seven attempts he records as having been made to secure the fusion of an egg of one of these with the sperm of the other, but, as he observes, most of the eggs "looked bad," that is, incapable of fertilization, so that his main conclusion rests on a few attempts to cross two species which a knowledge of the wild plants would have warned him not to use. It is to be regretted that he did not try to cross *Dryopteris cristata* with *Dryopteris marginalis*.

He reports four negative attempts to cross *Asplenium platyneuron* (L.) Oakes with *Camptosorus rhizophyllus* (L.) Link, between

[1] *Bot. Gaz.*, 49: 340–370, 1910.

which a natural suspected hybrid is known, a duplicate of which Miss Slosson produced culturally Most of his experiments at crossing were made with species in unrelated genera, *e g*, *Pteris* and *Athyrium*, two genera belonging in entirely different tribes. Also, he cites as the best evidence previous to his paper the work of O Voegler, who was unable to obtain fusion between the sperms and eggs of several pairs of unrelated fern genera, some of them genera from very distinct families, *e. g*, *Ceratopteris* and *Dicksonia*, *Dicksonia* and *Nephrolepis*, et al.

The case, then, for fern hybrids, stands just where it did and is based on facts which require reasonable explanation The evidence favoring hybrids has been fully presented, and does not need recapitulation It is quite true that experimental proof of the kind attempted by Hoyt and Voegler is lacking. No one has ever observed the development of a suspected hybrid from before the period of fusion of the gametes But such evidence is not usually required in cases of reputed hybridity. The arguments advanced by Mr. Hoyt against fern hybridity apply with practically equal force to most cases of accepted hybridity among flowering plants and in animals.

In conclusion, then, these reputed fern hybrids possess in all respects the characters generally recognized as characteristic of hybrids The existence of these plants demands some explanation, and their identification as hybrids furnishes the simplest and most reasonable one yet offered

RALPH C. BENEDICT

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE AND AFFILIATED SOCIETIES
SECTION B—PHYSICS

THE annual meeting of the American Association for the Advancement of Science, Section B, Physics, was held in the physical laboratory of the University of Minnesota, at Minneapolis, December 28–30, 1910 It was a joint meeting with the American Physical Society Three forenoon and three afternoon sessions were held Of these, two were "general interest" sessions, in charge of the officers of Section B and four were occupied with the reading of research papers, in charge of the American Physical Society.

The presiding officers were Dr E B Rosa, vice president of Section B, and Professor Henry Crew, president of the Physical Society At a short business session of Section B Professor O M Stewart was elected a member of the council, Professors A Zeleny and K E Guthe members of the sectional committee and Professor G W Stewart a member of the general committee

All sessions were held in the lecture room of the Physics Building of the University of Minnesota The dinner on Thursday evening with the mathematicians and engineers at the Commercial Club was a very pleasant and enjoyable occasion.

The officers for the next annual meeting, to be held in Washington during the convocation week of 1911–12, are as follows

Vice president and Chairman of Section B—Professor R A Millikan, University of Chicago.

Retiring Vice president—Dr Edward B Rosa, Bureau of Standards, Washington

Secretary—Professor Alfred D Cole, Ohio State University, Columbus

Members of the Sectional Committee—E B Rosa, R A Millikan, A D Cole, K E Guthe, A P Carman, G F Hull, E L Nichols, A Zeleny

The address of the retiring chairman of Section B, Dr L A Bauer, was given Thursday afternoon on the subject "The Broader Aspects of Research in Terrestrial Magnetism" This was a joint session with Section D, whose vice-presidential address was delivered at the same time by Professor J F Hayford, on "The Relation of Isostasy to Geodesy, Geology and Geophysics" The former of these addresses is presented in full in SCIENCE, January 13, 1911, and the other will be published soon

At the other general interest session the following program was presented

"Recent Advances in Phosphorescence and Fluorescence," Professor Edw L Nichols, Cornell University

"The Isolation of Ions," Professor R. A Millikan, University of Chicago.

"The International Electric Units" (report on changes to go into effect January, 1911), Dr E B Rosa, Bureau of Standards, Washington

"Osborne-Reynolds's Theory of Gravitation," John Mackenzie, M.E, Minneapolis

Abstracts of three of these papers follow (That of Professor E L Nichols will probably appear in the next issue)

The Isolation of Ions: Professor R. A. MILLIKAN.

This paper presented the methods used and the results obtained thus far in the work on the properties of isolated ions. It contained a more complete discussion of the material which was summarized in the issue of SCIENCE of September 30, 1910, and in addition new results obtained in collaboration with Mr. Harvey Fletcher—(1) on the question of valency in gaseous ionization, (2) on the causes of the irregularities obtained by Ehrenhaft in Vienna in his recent work on *e*. The new work only is here briefly summarized. The tabulated experimental data upon which the conclusions rest are soon to be published elsewhere.

1. In the work previously published it was conclusively shown that the great majority of atmospheric ions carry the elementary electrical charge, but there seemed to be some evidence that ions of larger valency were occasionally formed. This evidence was found in the fact that an oil drop suspended in a strong electrical field would occasionally catch, under the influence of radium, two or three elementary charges at once *when the field was on*.

The only preceding evidence in favor of the existence of valency in gaseous ionization is contained in the experiments of Townsend[1] and of Frank and Westphal,[2] which seemed to their authors to establish the production of some doubly valent positive ions by X rays, but not by other ionizing agents.

We accordingly suspended minute drops of oil in an electrical field and produced a thin sheet of X ray ionization in the air just beneath the drop, but no rays were allowed to fall upon the drop itself. The drops experimented upon were positively charged and the direction of the field was such that only positively charged ions could be thrown upon them. *Although we used rays of varying degrees of hardness we found in 125 catches not one which represented the advent of a multiple charge upon the drop.* These experiments present therefore direct, definite, unmistakable proof that the act of ionization of air by primary X-rays, even when these rays are of extreme hardness, consists in the separation of one single elementary charge from a neutral molecule.

[1] *Proc. Roy. Soc.*, 80, p. 207, 1908, 81, p. 464, 1908, and 82, p. 18, 1909.

[2] *Verh. d. D. Phys. Ges.*, März, 1909, and Juli, 1909.

When β rays of radium were used as the ionizing agent it was occasionally found possible, as in the work previously reported, to catch at once upon a single drop two or three elementary charges, *provided the drops were of sufficient size, but when the drops were very small we caught only singles.* This shows we think that all of the double and treble catches heretofore observed were due to the simultaneous catching by a large oil drop of two or three ions coming from two or three different molecules rather than to the separation from a single molecule of two or three elementary charges. In other words the capture of a number of elementary charges at once upon large drops furnishes no argument for the production of ions carrying two or more elementary charges, unless similar results can be obtained with small drops, and this we never found to be the case. Since it was only in the case of X rays that evidence for valency in gaseous ionization had been previously found *the present experiments seem to remove all ground for supposing that the act of ionization of a gas ever consists in the expulsion from a single molecule of more than one elementary electrical charge.*

2. When we used oil drops of smaller radius than about .00004 cm. we found that the remarkable consistency in the successive values of the times of fall under gravity shown in the work previously published (see SCIENCE, September 30) was replaced by greater and greater irregularities as the drops became smaller and as the distance between the cross hairs was diminished. The explanation lies in the fact that the displacements due to Brownian movements become in such cases comparable with the displacements produced by gravity during the time of observation. The correctness of this explanation is proved conclusively by tables prepared by Mr. Fletcher which show that the observed distribution of "times of fall" between fixed cross hairs .07 mm. apart agrees perfectly with the distribution of these times *computed* from the theory of probability as applied to Brownian movements. These considerations offer a complete explanation of the irregularities observed by Ehrenhaft, since he used a cross hair distance of about the value mentioned above and worked with particles the radii of which were on the average about one fifth of those of our smallest drops previously reported upon.

Ehrenhaft's failure to observe Brownian movements with platinum and gold particles while he

saw them clearly with "phosphornebel" is presumably due to the fact that, the kinetic energy of agitation of all particles being the same, the *velocity* of agitation of a platinum particle would be but about one fifth of that of a particle of like size in a cloud of phosphorus despite the fact that, as shown by Einstein's formula,

$$\overline{X}^2 = \frac{RT}{N 3\pi a\mu}\tau,$$

the displacement along X in a time τ would be the same for the two particles In other words, while the "drift" of a Brownian particle is inversely proportional to its radius and *independent of its mass*, the "instantaneous speed" of a particle of given radius is inversely proportional to the square root of its mass There is then nothing whatever in Ehrenhaft's work to raise a suspicion as to the correctness of any of the conclusions which have been drawn from our observations

The International Electrical Units Dr E B ROSA

The international electrical units current in all countries throughout the world are based upon the definitions and numerical values adopted at Chicago in the International Electrical Congress of 1893, except that the numerical value of the standard cell, adopted by Germany and some other countries, was slightly different from that recommended by the congress, which latter value was legally adopted in America, England, France and some other countries In order to secure international uniformity so that the ampere and the volt, as well as the ohm, should be the same in every country, an international research was carried on at the Bureau of Standards, during April and May of last year, in which the standards of the national laboratories of England, France and America were compared and the silver voltameter was investigated. As a result of this cooperative effort, the International Committee on Electrical Units and Standards has agreed to recommend to all the governments represented in that committee the adoption of a new value for the Weston Normal cell, which has the effect of changing the numerical value of the international volt and also of the international ampere The new value of the Weston Normal cell, at 20° C, is 1 0183 The previous value in America was 1 0191, whereas in Germany it was 1 0186, and in England for the last two years it has been 1 0184 although previously it was higher than the value in this country There will be, as soon as the new value has been generally adopted, international uniformity with respect to the value of the units of resistance, current, voltage and power It will, of course, require some time before the new values come into general use, although it is expected that they will be officially adopted in all countries at an early date The Bureau of Standards adopted the new value January 1, 1911, and certificates issued by the bureau after that date will be in terms of the new units The difference is, of course, inappreciable in ordinary engineering operations, but is very important in precise measurements, and is appreciable even in photometric measurements of electric lamps, in which the voltage or current, or both, are given

Osborne-Reynolds's Theory of Gravitation Mr JOHN MACKENZIE, M E, Minneapolis

In contrast with the ordinary view that space is filled with an ether of very low density, Reynolds's view is that space is filled with a granular medium of very high density The grains are small, hard spheres The density of this medium is 10,000 times that of water The grains are usually arranged in "normal piling" Where matter exists this arrangement is disturbed and a less number of grains occupies the same space This is "abnormal piling" Matter is then negative mass. An atom of matter consists of a nucleus of grains in normal piling surrounded by a shell of grains in "abnormal piling"

The grains have motion relatively to one another, but the mean path of the motion is only a very small fraction of their diameter This motion renders the medium elastic An experiment with billiard balls was used to illustrate mass motion in space, defined as a "coming in of grains in front and leaving of grains in the rear"

To illustrate the difference between normal and abnormal piling of grains a rubber balloon filled with sand and water was subjected to pressure by placing a 75-pound weight upon it The sinking of the liquid in an attached manometer tube showed that the addition of the weight *increased* the total volume of the intergranular spaces occupied by the water.

Reynolds holds that there is no attraction residing in masses of matter, but where abnormal piling (bodies of matter) exist, the pressure of the surrounding medium tends to restore normal piling and incidentally masses are driven together. This is gravitation

The theory is also applied to the explanation of cohesion, electricity, magnetism, light and other physical phenomena.

At the joint sessions for the reading of research papers the following list was presented

"The Ratio of the Two Heat Capacities of Carbon Dioxide as a Function of the Pressure and the Temperature," A. G. Worthing, University of Michigan.

"On the Adiabatic Expansion and Porous Plug Effect in Water between 0° and 40°," John R. Roebuck, University of Wisconsin.

"The Acoustic Shadow of a Sphere, the Theory and Certain Practical Applications," G. W. Stewart, State University of Iowa.

"On the Function of Rest in Restoring a Platinum-iridium Wire to its Annealed Condition," L. P. Sieg, State University of Iowa.

"The Nature of the Recovery of Light-positive and Light-negative Selenium," F. C. Brown, State University of Iowa.

"On the Fluorescence Spectra of the Uranyl Salts and the Structure of Luminescence Spectra in General," Edward L. Nichols and Ernest Merritt, Cornell University.

"The Effect of Red and Infra-red on the Decay of Phosphorescence in Zinc Sulphide," Herbert E. Ives and M. Luckiesh, National Electric Light Association, Cleveland, O.

"A Probable Explanation of the Irregularities obtained by Ehrenhaft and Przibram in their Work on the Value of the Elementary Electrical

Charge," Harvey Fletcher, University of Chicago

"Note on a Form of Spectrophotometer," Edward L. Nichols and Ernest Merritt, Cornell University.

A. D. COLE,
Secretary, Section B

SECTION G—BOTANY

AT the convocation week meetings in Minneapolis, Section G held two sessions, one on Wednesday afternoon, December 28, and the other on Friday morning, December 30, under the vice presidency of Professor R. A. Harper. Dr. William Crocker served as secretary in the absence of the regular secretary, Dr. Henry C. Cowles. The customary address of the retiring vice president was necessarily omitted, owing to the death of Professor Penhallow. The program consisted of four special addresses and a number of technical papers, abstracts of which appear below.

The section unanimously adopted the following resolution regarding the death of Vice president Penhallow: The botanists of the American Association for the Advancement of Science note with sorrow the absence from our meetings of David Pearce Penhallow, long a member of the association and a year ago the vice-president for the Section of Botany. We shall miss his tall impressive figure, his kindly voice and his keen and discriminating discussion. We here inscribe upon the minutes of the Section of Botany this tribute to his worth, and request the council of the association to make an appropriate entry upon its record.

Upon motion of Professor Newcombe, it was unanimously voted to request the council to appoint a committee to investigate the conditions for research in the Bureau of Plant Industry.

The following officers were chosen:

Vice president—Professor F. C. Newcombe.

Member of the Council—Professor F. C. Newcombe.

Member of the Sectional Committee (five years)—Professor L. H. Pammel.

Member of the Sectional Committee (one year, to fill the vacancy caused by the death of Professor Barnes)—Professor L. R. Jones.

Member of the General Committee—Professor C. E. Allen.

SPECIAL ADDRESSES

Imperfect Fungi as Causes of Wheat-sick Lands and of Deterioration in the Quality and Yield of Wheat: H. L. BOLLEY (abstract below).

The Organization of the Fruit-bodies of Hymenomycetes: A. H. REGINALD BULLER.

A Summary of Ecological Results from Colorado. FREDERIC E. CLEMENTS.

A South Sea Botanical Trip: JOSEPHINE E. TILDEN.

ABSTRACTS

The Work of Imperfect Fungi in Cereal Crop Deterioration. HENRY L. BOLLEY.

This paper gives an outline of experiments conducted at the North Dakota Agricultural College, dealing with the relation of the imperfect fungi in cereal cropping.

The essential conclusions may be summarized about as follows: the soils of the older wheat areas of the northwest are in the same sort of sanitary condition as the old flax cropped lands and may quite properly be spoken of as wheat-sick or wheat tired in the same sense as has previously been shown for flax lands. Wheat and other cereal lands are not necessarily depleted chemically as indicated by many agricultural and chemical writers, but may be only incapable of producing proper yields because of poor sanitary conditions in the soil or in the seed.

Soil and seed born diseases have been and are the agents which vitiate the conclusions of many well planned schemes of agriculture, as, for example, in fertiliser trials and crop rotations. These diseases, in large measure, account for the types of soil deterioration which agriculturists have had largely under discussion, much of the supposed improvement which has been described by such writers as applicable to special systems of cropping and of soil fertilizing have, in large measure, been due to bettered sanitary conditions rather than especially improved conditions as to soil fertility.

The genera of fungi which have been worked out as destructive to flax, wheat, oats and barley are found to belong to the old group of *Fungi imperfecti*. Of these the chief ones are *Helminthosporium*, *Colletotrichum*, *Fusarium*, *Macrosporium* and *Alternaria*.

There may be several species of each of these different genera at work. By cross infection, it is found that some of the kinds which attack wheat also attack barley. It is particularly interesting to note that practically all of the kinds which attack wheat also attack quack-grass. This accounts in large measure for the destructive influences which quack-grass has upon the development of the young cereal crop over quack grass areas.

Chief among the lines of work which have en-

abled the investigators to arrive at definite conclusions, has been the development of a disease propagation garden whereby the struggle for existence of the crop plants against great odds has been carefully noted and the attacking plants observed

In summarizing, attention is called to the bearings of these findings upon agriculture and upon the various lines of investigation Proper consideration of sanitary methods of handling soil and seed will prove a great boon to cereal crop growers but in order to accomplish this, it may be necessary to rearrange the methods of fertilizing soils and our systems of crop rotations These observations regarding the persistence of disease in the seed and in the soil will, of necessity, materially change our ideas as to why one crop does better after than before some other crop These observations, it is thought, explain many of the anomalies of farm cropping why certain methods of manuring result in shrivelling of seed wheat, why the attacks of rust are so destructive, why proper seed treatment has always resulted in better yields than could be explained by the presence or absence of smut alone, why the corn crop has proved to be such a beneficial crop to precede wheat, etc

In closing, attention is called to the extensive work of the Bureau of Soils of the Department of Agriculture upon so-called toxins in the soil, the troubles which they describe may not, of necessity, rest primarily in the soils Before material progress is made in the amelioration of conditions of cereal agriculture, proper consideration of soil and seed sanitation will prove to be the center about which great modifications in our present methods of agriculture must be shaped

The Succession of Vegetation in Ohio Lakes and Ponds ALFRED DACHNOWSKI.

Along the line of "watersheds" in Ohio are a number of lakes and ponds in various stages of "filling" Almost throughout, the surface vegetation is one that is common to bogs In relatively undisturbed areas there is a zonal arrangement An attempt is made at a classification of the formations, and a formulation of the laws of succession involved in the comparative study.

Forest Dynamics on Isle Royale, Lake Superior WILLIAM S COOPER

The dominant forest of Isle Royale is composed mainly of three tree species—balsam fir, paper birch, white spruce The relations of these to each other are as follows Spruce and birch form a small proportion of the forest if all ages are considered, but a large proportion of the mature stand The few large trees of these species are very conspicuous, while young ones are hard to find Balsams of all sizes, especially small, are exceedingly numerous The appearance is therefore of rapid succession, the balsam succeeding the other species.

Quadrat studies of selected areas, with the ages of all trees in the quadrats determined, shows that this appearance is deceptive The forest as a whole is in equilibrium, but a given area is continually changing in composition and in the relative proportions of the different tree species The changes are due primarily to the fact that all three species require considerable light during their early stages One generation in a given area prevents reproduction until maturity or some accidental cause brings about its destruction Windfall, by allowing light to reach the ground, is the commonest cause of the beginning of a new generation In windfall areas young tree growth soon springs up, usually predominantly balsam, owing to the ready germination of this species Balsam never becomes predominant in the mature stand, in spite of high reproduction, because of high mortality The reproduction of birch and spruce is low, but their mortality is also low

The result of these processes is that equilibrium is maintained in the forest as a whole The dominant forest is therefore the Climax Forest of the island

Observations on the Underground Stems of Symplocarpus and Lysichiton · C O ROSENDAHL

The underground stems of *Symplocarpus fœtidus* and *Lysichiton camtchatcense* are true sympodia, although the fact is not readily perceived on account of their thickness They grow very slowly, adding only from 3–8 mm. to their length yearly

On full-grown plants, five to six renewal shoots, or joints, of the sympodium are produced each year In *Symplocarpus* each renewal shoot or joint bears two foliage leaves, a spathe and an inflorescence. In *Lysichiton* each joint bears in addition two bracteal leaves, and the last 1–3 leaves in the fall are much reduced foliage leaves, *i e*, green leaves with very small laminæ, in *Symplocarpus* the first 2–3 leaves to appear in the spring are scale leaves

Symplocarpus sends up and matures only 1–2 inflorescences a year. The others become arrested and remain in between the broad bases of the foliage leaves *Lysichiton*, on the other hand, matures from 2–4 inflorescences yearly

The habit of these two aroids in producing from 2–5 inflorescences in excess of the number they are capable of maturing each year is to be explained in the light of their tropical origin and in their previous more southerly range

Some Effects of Severe Freezing upon Vegetation in a Condition of Active Growth F K. BUTTERS and C. O. ROSENDAHL

On the night of April 15, 1910, the temperature at Minneapolis fell to 27° F, and a week later to 19° F with a high wind At the time of these frosts vegetation was in an advanced state, many trees were in full leaf, and nearly all others in active growth Observations were made upon about seventy species of woody and herbaceous plants It was found that besides the injury due directly to cold, much mechanical injury resulted from loss of turgidity in succulent young shoots during the early stages of freezing, and from the extreme brittleness of hard frozen leaves and twigs which the wind snapped off in great numbers The second freeze injured many plants which were not hurt by the first one About 42 per cent of woody species lost practically all their foliage, only about 10 per cent were relatively uninjured Mature leaves and those just unfolding from the bud were less injured than half-grown leaves of the same plant In about 60 per cent of the species the twigs of the new growth were killed or severely injured In about 15 per cent the twigs of the past season's growth, and in a few instances older twigs, were injured Flower buds were somewhat more tender, open flowers and fruits much more tender than vegetative parts Damage to native herbaceous plants was mainly mechanical, and relatively slight except in the case of open flowers and fruits A few weeks afterwards herbaceous vegetation appeared normal while woody plants had just begun to recuperate The most usual types of recuperation in trees and shrubs were (1) when the twigs were uninjured and the terminal bud intact, this often made a further growth bearing a new crop of leaves, (2) when the outer parts of the new twigs were destroyed while the basal parts remained intact, lateral shoots often arose from the leaf axils of these uninjured portions either with or without the intervention of scaly buds, (3) many latent buds started into growth upon the woody twigs, sometimes upon those several years old In some cases all these methods of recuperation appeared in the same plant.

Color Photography in Botanical Work. FRANCIS RAMALEY

Botanists can make use of the new color photography especially in studies of ecology and plant breeding Many features of vegetation are brought out much more clearly than by ordinary photography Thus, a moor with scattered shrubs or a lake-margin surrounded with belts of different plants can be well shown In plant-breeding experiments the appearance of the different hybrids and extracted forms can be reproduced with much faithfulness Colored plates from books are easily reproduced upon lantern slides The exposure required is about 200 times that for an extra rapid isochromatic plate Hence no "snap shots" can be taken, but if the light is good there need be no difficulty in securing good results Development can be carried out in an ordinary dark room The solutions used are inexpensive and easily prepared

Respiration (CO_2 Production) in Air, in Nitrogen and in Hydrogen B M DUGGAR and GEORGE R HILL, JR

The experiments reported give data respecting the rate, continuance and decline of anaerobic respiration (CO_2 production) in nitrogen and hydrogen as compared with aerobic respiration under otherwise similar conditions The plant materials used were slices of sugar beet and germinating seed Special attention is also drawn to the importance of an available nitrogen supply for other physiological purposes

The Flora of the Olympic Peninsula, Washington ALBERT B REAGAN

The Olympic peninsula in northwest Washington comprises a wide coastal strip bordering on the Pacific Ocean, the Strait of Juan de Fuca and Puget Sound, surrounding a totally isolated, central high area termed the Olympic Mountains These occupy an eroded domed area in the east central part of the peninsula, with a western limb extending in declining altitude to Cape Flattery The peaks in the central area range from 6,000 to 8,150 feet in height, Mount Olympus being the highest peak The domed surface causes a radial drainage in all directions, but the larger streams flow into the Pacific

This peninsula with its lofty peaks stands first in the path of the moisture-bearing southwesterly winds from the Pacific, hence the precipitation is great, at the coast it is usually rain, in the mountains snow The precipitation averages 40 inches north and east of the mountains; west of the mountains at an elevation of 3,000 feet, about 80 inches; and in the Pacific and upper-Strait-Flattery region, 100 to 1?0 inches The climate,

also, is controlled by the prevailing warm winds from the western ocean, at the coast line snow is seldom seen

Under such an equable climate and abundance of rainfall, the peninsula, with few exceptions, is the most densely forested region in our country, and smaller plants do equally well Of course as one approaches the mountains the forest becomes less dense till the timber line is reached, but in the reverse proportion the flowering herbs at the same time increase in number and beauty The region in the lower levels is a jungle of trees, shrubs and entangled vines

About 200 square miles of the timbered area has been burned over, 260 square miles is naturally timberless, lying just at timber line; and 150 square miles consist of ice and rocks

The most conspicuous plants of the peninsula are red fir (*Pseudotsuga taxifolia*), lovely fir (*Abies amabilis*), subalpine fir (*Abies lasiocarpa*), white pine (*Pinus monticola*), red cedar (*Thuja plicata*), Alaska cedar (*Chamæcyparis nootkatensis*), Sitka spruce (*Picea sitchensis*), Merten's hemlock (*Tsuga Mertensiana*), vine maple (*Acer circinatum*), maple (*Acer macrophyllum*), alder (*Alnus oregona*), cottonwood (*Populus trichocarpa*), dogwood (*Cornus Nuttallii*), thimble berry (*Rubus parviflorus*), salmon berry (*R. spectabilis*), raspberry (*R leucodermis*), red elderberry (*Sambucus callicarpa*), red huckleberry (*Vaccinium parvifolium*), salal (*Gaultheria shallon*), Oregon grape (*Berberis nervosa*), fireweed (*Epilobium spicatum*), bracken fern (*Pteridium*), blue huckleberry (*Vaccinium ovalifolium*) and devil's club (*Echinopanax horridum*)

Of the plants of the region, the most conspicuous are the forest trees, which here reach gigantic proportions. Principal among these are fir, spruce, hemlock and cedar ranging from 200 to 400 feet in height, 90 feet clear of limbs, and from 10 to 13 feet in diameter, or more (the cedars ranging from 30 to even 50 feet in some instances) Intermingled with these trees is a profusion of shrubbery so dense in the coast districts that it is difficult to traverse the region. The estimated timber aggregates more than 70,000,000 M feet B.M., or enough timber to supply the entire United States's demand for more than two years.

The plants so far identified in the peninsula number 689

Twin Hybrids in Œnothera, with a Suggestion concerning their Explanation: R. R. Gates.

A large number of crosses were made, confirming in general the type of behavior in *Œnothera* called by de Vries twin hybrids, and adding new crosses which have not previously been made When a member of the *Onagra* group of species of *Œnothera* is pollinated by *O Lamarckiana* or one of its mutants, two types are produced known as *læta* and *velutina*, the former having broad and smooth leaves, the latter narrow, furrow-shaped and hairy leaves These types resemble each other in the different crosses, and both usually breed true There is a similar dimorphism in cultures of *O lævifolia*, broad leaved and narrow-leaved types occurring In cultures of forms which probably belong to *O muricata* (having smaller flowers than *O biennis*), from wild seeds collected in Nova Scotia, at St John, N B, and at Winnipeg, a similar dimorphism is found to occur, *i e*, broad leaved and narrow-leaved types, although the races do not all agree in other particulars The Winnipeg plants came from seeds of one individual. There is therefore a marked dimorphism of some of the forms in the wild condition, and this may account for the occurrence of similar twin types in crosses in which *O biennis* is the female parent, the condition being transmitted in the eggs, but not usually through the pollen.

The Sand-dune Flora of Iowa. B. Shimek

A discussion of the distribution and the physiographic features of the limited dune areas of the state is given The flora of the sand dunes is presented and the fact is brought out that while a limited number of species may be considered as characteristic of the dunes, the greater part of the flora is identical with that of the drier prairies

On the Relation of the Living Cells to Transpiration and Sap-flow in Cyperus: James Bertram Overton.

Experiments in which cut stems of *Cyperus* are placed in water show that withering occurs sooner than when a certain portion, not to exceed 20 cm., has been killed with steam and the killed stems left in connection with the roots When 20 cm. of the stem are killed with steam the leaves wither in about eight days, or in about the same time as control plants. It has been found that the longer the portion killed by steam the sooner the leaves above wither and dry When 25–30 cm. of the stem are killed with steam, the leaves wither in three to five days, no matter how long the section killed with steam may be. The leaves on steamed stems never wither quite so quickly

as those on stems cut and placed in water, but under the same conditions of light, temperature and air moisture. In this plant sufficient water to keep the leaves turgid for three to eighteen days will rise through a stem 15–60 cm high, with a section 5–60 cm. long killed with steam Experiments show that a certain amount of water is raised through the steamed portions, but that it gradually diminishes in quantity from day to day, until the leaves become air dry The diminished water supply is partly due to a partial blocking of the vessels with a gum-like substance, which probably owes its origin to the disorganization of the contents of the sieve tubes caused by heating the stems The withering of the leaves above the steamed portion is probably caused by the action of deleterious substances introduced into them from the dead cells more than from lack of water The poisonous substances are probably disorganization products caused by steaming the stems The withering leaves above a steamed portion of the stem show all of the symptoms of dying, namely, rapid loss of water directly after treatment, then a more uniform loss, rounding up and discoloration of the chloroplasts and contraction of the protoplasts The leaves apparently die, not so much from lack of water supply, as on account of the death of the cells from other causes It is evident from experiments that the steaming method of killing portions of the stems is not a satisfactory one in order to settle the question of the relation of the living cells to sap flow Other methods have been used. Killing a portion of the stem by applying wax heated to 110° C. causes less apparent disorganization of the cells of the stems, less injury to the leaves above and does not cause a marked immediate decrease in the amount of transpiration

An Undescribed Type of Elodea Flower: Robert Bradford Wylie

An unusual (and apparently undescribed) type of staminate flower was collected by the writer from East Okoboji Lake, Iowa, during the summers of 1909 and 1910. In this strain, which occurs abundantly in the locality, the axis of the staminate flower elongates rapidly at maturity, pushes out of the spathe and carries the pollen-bearing flower to the surface of the water, where it opens still attached to the plant. The degree of elongation may be as great as in the pistillate flower While the general appearance of the two flowers is similar, and the habits of reaching the surface of the water are biologically alike, the parts concerned are not homologous The elongated portion of the staminate flower is the axis below the floral parts, while that of the pistillate flower is the complex above the ovary in epigynous flowers called the "floral tube" In the opinion of the writer the form deserves specific rank, and the name *Philotria Iowensis* (*Elodea Iowensis*) is proposed

The Flora of a Saline Lake. M A Brannon

This report is based upon a study of Devil's Lake, situated in Benson and Ramsey counties, North Dakota It is a saline lake in the lowest portion of an inland drainage basin comprising about 4,000 square miles The lake has lowered about 14 feet within 27 years with the attendant results of receding shore line, separation of the former lake into divisions and an increase in the salinity of the water

Waves and the longitudinal and vertical currents cause thorough and rapid distribution of the phyto plankton in which representatives of the Myrophyceæ predominate

Ruppia maritima is the only spermatophyte found in Devil's Lake It grows in profusion on submerged terraces along shores protected by high land terraces

Enteromorpha prolifera, various species of *Cladophora*, and some of the Protococcales are the only Clorophyceæ found in this saline lake.

A study of ecological factors has been conducted with reference to pulsation in plant multiplication and in connection with inhibition of plants growing in adjacent bodies of sweet water.

Nodularia spumigena var *litoria* gave the following record May 29, 1910, there were three to five per cubic centimeter, August 18 there were several hundred filaments per cubic centimeter and on November 1 only two to three per cubic centimeter

This pulsation was believed to be caused largely by the increased heat The temperature readings on May 29 were 14° C, August 18 20° C and November 1 11° C. The maximum portion of the curve was coincident with increased light action and increased wave and current action of the lake.

Spirogyra and *Chara* were used in the inhibition experiments and the results indicate that loss of turgidity when immersed in saline solutions was largely responsible for the non-existence of these and other forms in Devil's Lake. *Enteromorpha* and *Cladophora* are capable of standing ten to thirteen per cent. salt solutions, according to Oltmanns, hence these forms are not inhibited

from Devil's Lake but are present in great quantities. Detailed physical and chemical experiments await further investigations, but present information does not indicate that the toxic action of salts is responsible for the Devil's Lake inhibition of plant forms growing in bodies of sweet water adjacent to Devil's Lake.

Nuclear Phenomena in the Basidium and in the Germinating Spores of Dacrymyces and Tremella: E. M. GILBERT.

The discovery of the fusion of two nuclei in the basidium and the further fact that the cells from which the basidia arise are binucleate, has made it of vital interest to discover the origin of this binucleate condition. The writer finds that the spores of certain species of *Dacrymyces* and *Exidia* are uninucleate and become in germination, successively two, four and eight celled, each cell being uninucleate. Germ tubes are then developed and a mycelium formed, the cells of which have a single nucleus. The binucleate condition does not then arise at the germination of the spore or in the young mycelium. Dangeard, Perrot and Maire find that the subhymenial cells of various forms are binucleate. The writer finds a nuclear fusion in the young basidia of *Exidia albida* and *Dacrymyces* sp. The double division of the fusion nucleus in species of *Exidia* and *Tremella* studied, suggests, in many of its features, that chromosome reduction occurs at this stage. Synapsis and diakinesis are well marked stages. The two spored basidia of *Dacrymyces* as noted by Juel and Dangeard raise an interesting question as to the method of reduction in this form.

The Organization of the Chromosomes in Carex: A. B. STOUT.

The visible structures in the resting nuclei in the root tip of *Carex aquatilis* and their behavior throughout mitosis make it plain that here the chromosomes are permanent individuals which can be identified not only in resting nuclei, but throughout the entire process of nuclear and cell division, except for a short time during the diaster stage when they are closely massed together.

The chromosomes are also arranged in a definite serial place relationship which is preserved throughout the late prophases and the equatorial plate stage. There is thus maintained throughout all stages of division a definite relative position of the chromosomes.

The spheroidal shape of the chromosomes is quite constant and uniform. There is, however, marked growth in their volume during early prophases until they reach their maximum size, which varies from 0.3 μ to 0.4 μ in diameter. This rather constant spheroidal shape facilitates the identification of the individual chromosomes throughout the various stages. At one stage in the late prophases the chain of chromosomes is tightly coiled about the nucleole.

This behavior of the chromosomes in *Carex* gives positive evidence in support of the view that chromosomes are permanent individuals with a definite and permanent relative arrangement in the nucleus.

THE UNIVERSITY OF CHICAGO

THE AMERICAN SOCIETY OF ZOOLOGISTS CENTRAL BRANCH

THE annual meeting of the American Society of Zoologists, Central Branch, was held in conjunction with Section F of the American Association for the Advancement of Science in Pillsbury Hall of the University of Minnesota, Minneapolis, Minn., on December 28, 29 and 30, 1910, Professor C. E. McClung, of the University of Kansas, presiding.

The committee on nomenclature appointed at the Iowa City meeting reported that it was making progress in the formulation of a plan

whereby the various zoological organizations of America can unite in an effort to influence the International Commission on Nomenclature in the direction of securing greater flexibility in the interpretation of its own rules. The committee was given power to perpetuate itself

The chair was authorized to appoint a committee whose function it shall be to recommend to the society plans for an agreement between its members regarding the form and manner of presenting papers for publication Such plans shall have for their purpose the aiding of other investigators in arriving at an understanding of the methods and conclusions of writers with the least possible expenditure of time and effort

Officers for the ensuing year were chosen as follows

President—George Lefevre, University of Missouri

Vice president—R H Walcott, University of Nebraska

Secretary-Treasurer—H V Neal, Knox College

Executive Committee—H B Ward, University of Illinois (for three years), Chancey Juday, University of Wisconsin, H W Norris, Grinnell College

The following, having received the votes of a majority of the executive committees of both branches, were elected to membership in the Central Branch Dr G W Tannreuther, University of Missouri, Dr A G Ruthven, University of Michigan, Dr R C Mullenix, Yankton College, Mr H Walton Clark, Bureau of Fisheries, Fairport, Iowa

The following are titles and abstracts of papers presented at the meeting·

Organ Inversion in Trematodes F D BARKER, University of Nebraska.

Situs inversus viscerum in varying degrees has long been known to occur in man This deviation from the normal position of organs also occurs in a number of animals such as the tadpoles, flatfishes and molluscs. Variation in the position of the genital organs or *sexual amphitypie* is very common in the trematodes From the examination of original specimens and the literature I have found this variation occurs in at least 26 different species, embracing 11 different genera of distomes and one genus of monostomes The percentage of *sexual amphitypie* varies from 3 per cent in some species to 50 per cent in others The degree of transposition of organs varies from the transposition of a single organ to that of six organs. In many cases other organs than the sexual organs are transposed, in which cases the term *situs inversus* is more applicable. Where only one or two organs are transposed this should be designated as *partial sexual amphitypie*

A number of theories as to the cause of *situs inversus* has been advanced, among which are "the preponderance of the omphalo mesenteric vein," "the persistence of the left venous trunks," "discontinuous substantive variation," "a condition essential to the existence of the organism," "inversion through sympathy"

Experimental work on incompletely separated blastomeres of the frog, sea-urchin, mollusc, etc, shows that such blastomeres give rise to twin embryos, one of which is a "mirror image" of the other This suggests the possibility that "mirror images" or *sexual amphitypie* in the trematodes may be due to the development of twin trematodes which have arisen from completely separated portions of the "germ balls" in the sporocyst or redia stages

Fuller account to be published later, place undetermined

Gametogenesis in Tænia serrata R T YOUNG, University of North Dakota

Testes and ovaries arise from undifferentiated parenchyma cells Oogonia and spermatogonia are similar in structure and appear to arise similarly No mitoses are found in the early stages of development of these cells Amitoses, while present, are too infrequent to account for the multiplication of the primitive sex cells, and it is probable, although not certainly demonstrable as yet, that increase is partly due to the development of nuclei either de novo or from chromidial extrusions from preexistent nuclei

The spermatocytes of the first order arise from the spermatogonia by an enlargement of the nucleus and the formation of a skein from its reticulum The spermatocytes fuse to form cytophores with subsequent breaking up of the skeins and commingling of the skein remnants with the cytoplasm of the latter The secondary spermatocytes arise in the cytophores either *de novo* or from the skein remnants of the first spermatocytes The spermatozoa are formed directly from the cytoplasm of the cytophores In oogenesis skeins are similarly formed subsequent to the growth period and similarly degenerate without the occurrence of later stages of mitosis at this time. As the ova are leaving the ovaries or after reaching the uterus an abortive maturation mitosis occurs, without however the appearance of polar bodies; the cell or cells which have been

occasionally interpreted as such, being yolk cells attached to the ova during or after their passage to the uterus. These observations support the view previously advanced that cytological processes in cestodes are degenerating in correspondence with the general degenerate character of these worms.

Full account to be published elsewhere

The Biology of the Sand-Hill Region of Nebraska. ROBERT H WOLCOTT, University of Nebraska

In SCIENCE for May 19, 1905, appeared a statement in regard to a faunal survey of this region which had been already inaugurated Soon after the publication of this statement, conditions arose which interfered with the further prosecution of this work, and in the five years which have intervened only occasional short trips to the region have been made During the past season, however, work was actively resumed by the collecting of water samples from the different lakes and the collection of additional data and specimens bearing on the topography and fauna of the lake region A preliminary chemical examination of these water samples shows that the lakes vary in strength of alkali, expressed in terms of CO_3 and HCO_3 ions, from 06 of a gram per liter to 1 61 grams per liter—a difference of more than 25 times The most highly alkaline of these lakes is not as alkaline as many other lakes which have been investigated in the far west, but the close proximity to one another, the exact similarity in every other respect than alkali content, and the fact that the alkalinity in the strongest of these lakes surpasses a percentage which apparently most of the forms present in the freshest lakes can not resist, seem to make it probable that the results of a careful qualitative analysis of the life of the different lakes will yield very interesting results Arrangements have been perfected whereby a party is to be maintained in the region throughout the coming summer, and it is expected that in this way a sufficient amount of material can be gathered to allow of the formal presentation of results, at least so far as certain phases of the work are concerned.

The Olfactory Organs and the Sense of Smell in Birds R M STRONG, the University of Chicago.

A report was given of a comparative study of the organs of smell in various groups of birds. Results of experimental studies of the olfactory sense in ring-doves were also described. Evidence was obtained in this work that at least many birds probably have an olfactory sense It is not likely, however, that the sense of smell is ever very keen in birds. A full account has been prepared for publication elsewhere.

Results of Breeding Experiments with Ring-Doves. R M. STRONG, the University of Chicago

Crossing experiments with white and blond ring doves were carried on during a period of five years In the first generation, the hybrids resembled one parent or the other in equal numbers. The blond hybrids were mostly males and the white hybrids were all females The original stock was found to breed true, but the blond hybrids behaved as heterozygotes A full account of the results obtained will appear later

The Cranial Nerves of Siren lacertina H W NORRIS, Grinnell College

The olfactory nerve is double. Anastomoses between the fifth and seventh nerves, general cutaneous fibers from the fifth and lateral line fibers from the seventh form a supra-orbital trunk, and similar fibers form an infra orbital trunk; from the latter general cutaneous and lateral line fibers unite with a branch of the ophthalmicus profundus to form a nerve that sends its lateral line fibers to innervate neuromasts at the end of the snout and its general cutaneous component to form an anastomosis with the ramus palatinus, between the alveolaris VII and the mandibularis V the characteristic anastomosis occurs only to the extent of a slight contact between the two nerves From the dorsal lateral line ganglion of the seventh nerve a nerve passes posteriorly to anastomose with the rami supratemporalis and auricularis X, suggestive of the condition in the Cyclostomata The rami alveolaris and palatinus arise by a common trunk from which is given off a so-called "posterior palatine" that connects with the ramus pretrematicus IX forming Jacobson's commissure The ramus communicans carries general cutaneous fibers only, from the tenth to the seventh nerve. Pretrematic rami of five branchial nerves are found. The ramus intestinalis recurrens X. is entirely motor, its usual sensory component having separated to form a distinct trunk. The hypoglossal nerve is formed from branches of the first and second spinal nerves. Full account to appear in Vol. 17, *Proceedings of the Iowa Academy of Science*, 1910.

The Innervation of the Lateral Line Organs in Amphiuma and Siren: H. W. NORRIS, Grinnell College.

Kingsbury's classification and grouping of the lateral line organs in amphibia is found to correspond in a general way to their innervation in *Amphiuma* and *Siren*, but it is evident that the external distribution of neuromasts is no exact indication of their innervation Much overlapping of groups occurs, and there appears to have taken place a considerable degree of migration of neuromasts from their points of origin. The occipital group of neuromasts is innervated not by the lateral line nerve of the trunk, as Kingsbury supposed, but by the rami supratemporalis and auricularis X The ramus lateralis VII in *Amphiuma*, contrary to the earlier opinion of the writer and of Drüner, has no connection with neuromasts The neuromasts in *Siren* have a much less typical arrangement than in *Amphiuma* Full account to appear in *Proceedings of the Iowa Academy of Science*, Vol 18, 1911, under the heading "The Lateral Line Organs of the Urodele Amphibians Distribution and Innervation"

A Review of Recent Work on the Development of the Sympathetic Nervous System ALBERT KUNTZ, University of Iowa

Poulton's Theory of the Origin of Mimicry in Certain Butterflies J. F ABBOTT, Washington University

A biometric study of the variation of the color pattern of butterflies of the two species of *Limenitis*, *arthemis* and *archippus*, captured in the same region in New York State fails to confirm Poulton's theory that the latter form has originated from the former by an expansion and migration through the agency of selection, of color patches existing in the ancestral type (*arthemis*) The selection hypothesis by itself would thus seem inadequate to explain the origin of the phenomenon.

Comparison of the Arrangement of Eggs in Nests of Japyx sp and Scutigerella immaculata · STEPHEN R WILLIAMS, Miami University.

A photograph of two specimens of *Japyx* sp guarding their eggs was shown The two egg-masses were placed, each in a cavity in decayed wood, in such a way that only a very few eggs were in contact with the substratum The rest were heaped upon these and touched nothing else in the cavity

The attending individuals died within twenty-four hours and the eggs never hatched, being attacked by fungus.

Precisely the same arrangement of the eggs is seen in *Scutigerella immaculata*, which occupies the same habitat The eggs are placed in a heap, few eggs only touching the moist decayed wood of the substratum and the rest above and around these. The female remains with the eggs to keep off fungi and animal parasites and no masses of eggs unattended by the female have hatched under laboratory conditions

When *Scutigerella* in the laboratory is unable to find a sufficiently secluded place to deposit the eggs they will be laid singly here and there. In every case, however, the single egg is fastened to the substratum as if in preparation for heaping others about it

Besides the well-known outward resemblances between *Japyx* and the Symphyla—the shape of the antennæ, the shape of the body, the presence of pairs of rudimentary legs on the segments of the abdomen—can these similar nesting habits not be considered as an additional indication of relationship?

The Vitalism-materialism Controversy · Can it be Ended? (vice presidential address) W E RITTER, University of California

On the Transition from Parthogenesis to Gamogenesis in Aphids S J HUNTER, University of Kansas

Observations on the conditions attending the appearance of the sexes in the aphid, *Toxoptera graminum*, now made continuously through four years, show that time of occurrence of sexes and attendant behavior of the agamic and intermediate forms continue as presented in a paper a year ago before the eastern branch.[1]

The problem of this year, beginning January last, was the addition of the woolly aphis to be studied under normal conditions, and an attempt to determine what bearing, if any, modifications in food supply might have on the *Toxoptera graminum* A duplicate series of experiments in charge of two careful observers were established last January under the following conditions in the laboratory. Wheat was germinated in three-inch pots and each treated continuously with—instead of water—solutions of a number of salts—seventeen in all, respectively. New pots of wheat, similarly treated, replaced those in which wheat succumbed to treatment.

Daily observations and records were made on each one of these experiments throughout the

[1] SCIENCE, N. S., Vol. XXXI., p 476, March 25, 1910.

entire year, and comparisons made with the stock growing in the laboratory. The wheat clearly showed the effect of the different treatments, but aphids did not manifest any significant change. When the sexual and intermediate forms began to appear on the regular stock in October they likewise began to appear on these experimental pots.

In the woolly aphis the agamic forms were wingless throughout the entire summer season. The first winged forms appeared September 19, and ceased to appear on December 6. The offspring of these winged forms are the true sexes. The first of these to appear was on December 25. These true sexes are wingless and in accordance with the observations of Von Baehr each female produces but one egg. All colonies do not produce winged forms and hence all colonies do not produce sexual forms. All winged forms of the woolly aphis do not produce offspring. Out of a series of nineteen isolated winged forms only eleven reproduced and those eleven brought forth twenty seven young composed of twenty one males and six females.

Thus far it appears difficult to correlate and establish external conditions which would appear to have a direct bearing on the transition from parthogenesis to gamogenesis in aphids.

In the two forms studied the sexes appear in the fall of the year and may be spoken of as seasonal. This is true also for a very large number of aphids whose behavior in this respect has been recorded by others. This naturally leads to a careful analysis of the conditions obtained at this period of the year. It is our purpose now to continue these studies throughout the next year, dealing chiefly with the questions of temperature and light.

On a Case of Parasitic Thoracopagus in a Frog: GEORGE WAGNER, University of Wisconsin.

An instance of a frog having three extra legs extending from an irregularly shaped bone overlying the sternum, the case was interpreted as representing what by students of teratology is known as an epigastrius (Schwalbe), or a parasitic epigastrius (Adami). The case is believed to be the first of its kind reported in an amphibian. A full account of it will be published later in the *Biological Bulletin*.

The Pomace Fly Bred in the Dark for 67 Generations: FERNANDUS PAYNE, University of Indiana.

The Proposed Laysan Island Expedition and Exhibit: C. C. NUTTING, University of Iowa.

The Origin of the Sex-cells in Necturus: BENNET M. ALLEN, University of Wisconsin.

The sex cells of this amphibian arise from that portion of the mesoderm which lies between the future myotome and the future lateral plate. This anlage was recognized as early in development as an early medullary plate stage, owing to the fact that it is noticeably thicker than the lateral plate region lateral to it, and that it is at the same time marked off from the anlage of the mesoblastic somites by a constriction that indicates the first point of division of the mesodermal sheet.

The mesodermal cells show very slight differences at this stage, being equally filled with yolk, and having nuclei in which I, thus far, have been unable to distinguish constant and important differences, nor has it been possible thus far to differentiate them from the nuclei of the endoderm. It is just possible that further work may enable me to distinguish them in this and in earlier stages, by the use of special staining methods.

While the outlines of this sex cell mass are vague at the outset, they become very clearly defined in later stages, when, first the myotome, and then the lateral plate tissues begin to use up their yolk material, while the sex-cells remain unchanged and do not divide. It then becomes evident that the sex-cell anlagen are continuous in the greater part of their extent, being somewhat interrupted only at their cranial and caudal ends.

At the stage with which this account begins, the Wolffian ducts have not yet been formed. So soon as they make their appearance, however, they lie immediately above and slightly medial to the sex cell anlagen. In still later stages, the latter are seen to shift toward the median line. This movement accompanies the growth of the lateral plates and appears to be caused by it. The sex-cell anlagen finally meet in the median line and the mesentery forms beneath them. They then migrate laterally to the anlagen of the sex-glands.

While it will be seen that this account is quite in agreement with Dustin's account of the origin of the sex-cells in *Triton*, and consequently at variance with the process described in my paper on the origin of the sex-cells in *Rana pipiens*, I have nothing whatever to retract from the observations and conclusions expressed in that paper. Repeated study of my old preparations and of many new ones have confirmed their accu-

racy Furthermore, the papers of King on *Bufo lentiginosus* and of Kuschakewitch on *Rana esculenta* have confirmed my work on *Rana pipiens* While Dustin strikes a discordant note in his account of the origin of the sex-cells of *Rana fusca* and *Bufo vulgaris*, it may not be wide of the mark to tentatively advance the view that the sex-cells arise in the Urodeles from that portion of the mesoderm between the anlage of the mesoblastic somites and lateral plate, while in the Anurans they arise from that part of the endoderm that forms the median portion of the roof of the archenteron. This is not inconsistent with the conception of the sex cells which is being more and more firmly established, namely, that they are cells preserved from early stages in an undifferentiated condition and that they are capable of considerable migration along radically different paths There must, as a matter of course, be a more or less close correspondence in these migration paths in closely allied forms, but radical differences might be expected in such fundamentally different groups as the Urodeles and the Anurans

Anatomical Illustration before Vesalius (with illustrations from original sources) W A LOCY, Northwestern University

On the Distribution in the United States and some Points in the Habits of Clinostomum marginatum HENRY LESLIE OSBORN, Hamline University

This trematode was first recorded in Europe by Rudolphi in 1809 under the name *Distomum marginatum* The following summary shows the records of its occurrence in this country with date, writer, name, host and infected part, and locality 1856, Leidy, *Clinostomum gracile, Esox*, intestine, Delaware River, 1877, Leidy, *Distomum galactosomum, Roccus lineatus*, Philadelphia, 1879, Wright, *Distomum gracile, Perca flavescens*, branchiostegal membranes, Toronto, 1879, Wright, *Distomum heterostomum, Botaurus minor*, mouth, Toronto; 1885, Looss, *Distomum reticulatum*, silurid fish encysted in muscle tissue, Porto Rico; 1895, MacCallum, *Distomum gracile*, frog, encysted in pectoral muscle, Toronto, 1897, MacCallum, *Distomum heterostomum, Ardea herodias*, mouth, Toronto; 1898, *Distomum gracile, Eupomotis pallidus*, pectoral fin and roof of mouth, Kansas City, Mo; 1901, Osborn, *Clinostomum marginatum, Micropterus dolomieu*, encysted in muscle, Nebish, Mich; 1901, Osborn, *Clinostomum marginatum, Ardea herodias*, throat, Nebish, Mich.; 1903, *Clinostomum marginatum, Rana virescens*, encysted in cœlom wall and subcutaneous lymph spaces, Saint Paul, Minn, 1903, Young, *Clinostomum marginatum, Micropterus dolomieu*, encysted in branchiostegal membranes and muscle, Troy, Ohio, 1904, Stafford, *Clinostomum gracile, Perca flavescens*, gills, Montreal Its distribution is thus shown to be very wide, as indicated by the names Philadelphia, Troy (Ohio), Kansas City, Saint Paul, Nebish, Toronto and Montreal And yet we do not know its primary host, the worm being virtually completely developed when found in the fish and frog It is a trematode of economic importance, since it infects the edible portion of one of our principal game fishes, though it is presumably not strictly harmful to man It is evidently very widely spread in northern and eastern United States and may be expected to be found outside the limits already noted as soon as search is made The habits of the worm were studied in the forms encysted in the bass The cyst is a perversion of the endomysial connective tissue and is wholly contributed by the host The worm in the cyst is bent twice on itself, the ventral surface being turned toward the inner surface of the cyst whose cavity is completely filled by the worm Immediately on escaping from the cyst the worm is very active indeed, its movements, besides many random and irregular ones, falling under two types a retraction of the anterior end, producing a club shaped front region possibly related with adhesion, and a thinning and flattening of the body such that its ventral surface becomes somewhat concave and the margins of the body assume the appearance of lateral fins. Neither of these two body forms were made practical use of by the worm, the body merely taking on the shape momentarily and then relaxing back at once into the resting form

The worms in the frog were studied at St. Paul They are not so much found in the muscle of the frog, their usual location in the fish, as in the cœlomic wall where the cysts lie, not in the muscular tissue, but between it and the peritoneum. The cysts, too, are very much larger than those in the fish and the worm is bent double within, the ventral surface being external. The cysts are similar in structure to those in the fish, being made up of fibrous tissue and supplied with a distinct capillary network

It is planned to publish this paper in the *Biological Bulletin*.

The Transmission of Trypanosoma lewisi by Rat Fleas (Ceratophyllus sp. and Pulex sp), with

Short Descriptions of Three New Herpetomonads. L. D. SWINGLE, Nebraska Wesleyan University.

The rat trypanosoma passes through a cycle of development in the digestive tract of rat fleas. After it is taken into the flea's stomach, it soon passes backwards into the intestine. The nucleus moves toward the posterior end, the blepharoplast toward the anterior end of the body and the undulating membrane is lost, so that a Crithidia results. Some of the individuals agglutinate by their flagellar ends and eventually form cysts. Others, by rounding off at the anterior ends, form cysts directly. In these the posterior end containing nucleus and blepharoplast remains very pointed. Forms resembling the "latent bodies" of *T. lewisi* were found in the crushed heads of fleas.

A case which might reasonably be interpreted as a conjugation of male and female forms was found.

The fleas harbor a natural flagellate, *Herpetomonas pattoni* n. sp. Two new herpetomonads are described: they are *Herpetomonas calliphoræ* n. sp. from *Calliphora coloradensis* and *Herpetomonas lineata* n. sp. from *Sarcophaga sarraceniæ*.

To be published in the *Journal of Infectious Diseases*.

The Nature and Origin of the Fish-fauna of the Guiana Plateau. C. H. EIGENMANN, University of Indiana.

Color Inheritance in Tumbler Pigeons. LEON J. COLE, University of Wisconsin.

From black tumbler pigeons crossed with red were produced in F_1 27 offspring, which were all black, with, however, reddish tips (often very conspicuous) on the feathers prior to the first molt. From these birds bred *inter se* segregation was obtained in F_2, which comprised 71 birds, of which 45 were black and 26 red. No explanation was offered for the departure from the Mendelian ratio. Furthermore, practically all these blacks in F_2 have reddish tips on the first feathers. This point was discussed in its relation to melanin oxidation and Mendelian inheritance.

Some results from other crosses were given.

Sex Ratio and other Reproduction Statistics in Tumbler Pigeons. LEON J. COLE, University of Wisconsin.

Statistics presented showed that of the two eggs laid by pigeons at a sitting each produces approximately an equal number of males and females, and that the chances are equal that the two eggs will produce birds of the same sex or birds of opposite sex. This corrects the popular notion that the two eggs of a sitting produce a pair of young (a male and a female) and that the first one laid usually, if not always, produces a male.

In 62 per cent. of 101 cases of tumblers the interval between the laying of the first egg and the second was 44 or 45 hours. Nevertheless, in a large percentage of cases the eggs hatch at approximately the same time.

The normal period of incubation is seventeen days, but birds allowed to sit on eggs which do not hatch will sometimes incubate up to thirty days.

(This paper and the preceding are based on experiments conducted at the Rhode Island Agricultural Experiment Station, the results of which will shortly be published in full by the station.)

A Note on the Metamorphosis of Lampsilis lævissimus. ROBERT E. COKER and THADDEUS SURBER, Fairport Biological Station.

The glochidium of *Lampsilis lævissimus* is of the "axe head" form similar to that of *L. alatus*, but without the hooks characteristic of the latter. The same form of glochidium is seen in *L. capax*, although in the shape of adult, *capax* is at an opposite extreme from *lævissimus*. Nevertheless, in certain significant taxonomic characters *lævissimus* and *capax* show agreement in the adult stage.

A few specimens of mussels in the stage of parasitism which show glochidial shells of the *lævissimus* form have been observed. These young mussels show a notable increase in size and a striking change of form as compared with the glochidial stage. It is not known that such marked changes occur in other species during the period of parasitism.

An Alpheus with Two Equal "Snapping" Chelæ. CHARLES ZELENY, University of Illinois.

Some Data concerning Dibothriocephalus latus in America, with Report of a Second Case of Infection Acquired in the United States. W. S. NICKERSON, University of Minnesota.

I have collected from physicians reports of the occurrence of the fish tape-worm (*Dibothriocephalus latus*) of man in 65 cases, 51 of which were in Minnesota. But six of these have been previously mentioned in literature. The hosts in two cases were Swedes, in one a Japanese, in two native born, and the others with few if any exceptions were Finns.

I have also to report a second case of *Dibo-*

thrococephalus infection acquired in this country. It occurred in a woman who was born and has always lived in Hennepin County, Minn., never having been out of the state except once for a visit to North Dakota. While there she ate dried and smoked fish (otherwise uncooked) and it was soon after her return home that she experienced symptoms attributable to the tape worm. The infection must therefore have occurred in America and from the eating of American fish.

Paragonimus in a Cat in Minneapolis: W. S. NICKERSON, University of Minnesota.

I wish to put on record the occurrence of *Paragonimus Kellicotti* in the lung of a cat from the grounds of the University of Minnesota. Three specimens were obtained.

An American Intermediate Host for Hymenolepis diminuta: W. S. NICKERSON, University of Minnesota.

The common tape-worm of the rat, *Hymenolepis diminuta*, is also an occasional human parasite, some fourteen cases having been reported. It has been shown in Europe that its cercocystis stage may be passed in several insects, the meal moth and its larva (*Asopia*), the earwig (*Anisolabis*), and beetles (*Akis* and *Scaurus*), *Asopia* being the form that commonly serves as intermediate host. In America an intermediate host has not been observed and attempts at experimental infection of our American meal worms have not been successful.

A case of infection of a child in Minnesota by *Hymenolepis diminuta* has come to my attention in which the circumstances suggested strongly that the diplopod *Julus* had been the intermediate host from which the child had become infected. Acting upon this hint I fed fragments of *Hymenolepis diminuta* to young diplopods, supposed at the time to be young julids. Some of these were found subsequently to be full of cercocystides agreeing fully with those figured by Grassi and Rovelli and which they demonstrated experimentally to be the young of *Hymenolepis diminuta*. Later I learned that my diplopods were *Fontaria virginia* Bollman of the family Polydermidæ.

In an attempt to repeat the experiment, using *Julus* instead of *Fontaria*, I was able to obtain but a single specimen of *Hymenolepis diminuta* with but few proglottides having ripe ova. In one of the specimens of *Julus* to which the proglottides were fed a few specimens of cercocystides were subsequently found which were of the same sort as those previously obtained from *Fontaria*.

The rearing of the adult worm (Hymenolepides) from the larvæ by feeding experiments was rendered impossible in both cases by the fact that the infected condition of the myriapods was not discovered until they were already dead. In view, however, of their complete agreement with the descriptions and figures given by Grassi and Rovelli of the larvæ of *Hymenolepis* and the way in which they were obtained there can be no doubt as to their identity.

These experiments show that at least two different genera belonging to the class Myriapoda may act as intermediate hosts for *Hymenolepis diminuta* in America. The intermediate hosts previously known in Europe are of the class Hexapoda.

Preliminary Account of the Early Development of Cirratulus grandis Verrill: JOHN W. SCOTT, Westport High School, Kansas City, Mo.

The common fringe worm of the Atlantic coast, at Woods Hole, is found in muddy ooze around the roots of eel grass. It is easily excited to oviposition, but few eggs will fertilize if deposited before 10 P.M. Eggs deposited during the night may be fertilized the next morning. The first polar body comes off in 10 minutes, and the second in 17 minutes. A yolk lobe is formed, may be constricted off, but is always reabsorbed. Unequal cleavage occurs at 49 minutes. The second cleavage, 8 minutes later, results in a three-celled stage. The entoderm appears to be separated at the first cleavage. The entoderm cell remains long undivided, and gastrulation takes place by overgrowth of other cells. The trochophore is scarcely able to leave the bottom and is never pelagic. At 51 hours it settles on the ventral side and moves like a flatworm, a ventral band of cilia is used for locomotion. Septa develop and disappear with the one exception found in the adult. An introvert arises as an infolding of the body wall posterior to the mouth, later a common opening serves for both. The introvert is used at this stage, chiefly for locomotion. The larva was kept until 20 days old.

An Accessory Chromosome in the Opossum: H. E. JORDAN, University of Virginia.

The number of chromosomes in equatorial plates of dividing spermatogonial and interstitial cells equals seventeen. Plasmosome present in resting primary spermatocyte. This stains intensely black in iron-hæmotoxylin, but only faintly green in Auerbach's stain (= methyl green + acid fuchsin). Plasmosome can not be traced into later

stages, but during synapsis a dark staining sharply contoured body (accessory chromosome) appears at point where the loops converge This point is always next the conspicuous centrosphere lying just outside of the nuclear wall Plasmosome believed to become accessory chromosome on basis of similarity of form, *i e*, bipartite character. In post synaptic stages, while the autosomes are still only slightly chromatic, the deeply chromatic monosome (accessory chromosome) always lies close to point where centrosphere is located

Equatorial plates of first maturation mitosis contain nine chromosomes (eight bivalent ordinary and one accessory chromosome) The accessory, both here and in earlier stages, appears bipartite, sometimes completely divided and separated The accessory passes undivided to one pole slightly in advance of the eight univalent ordinary chromosomes, the opposite pole receiving only eight chromosomes Two types of secondary spermatocytes are formed, one with a slightly chromatic nucleolus (= accessory), the other without Equatorial plates of second maturation mitoses show five chromosomes (four pairs of the eight univalents of last mitosis + one accessory) and four chromosomes, respectively In late telo phase the pairs are again resolved into nine and eight chromosomes, respectively Dimorphism of spermatids--metamorphosis into spermatozoa and the presence of chromidial elements—were also considered

This paper will be published in the *Journal of Morphology*

The Formation of the Spermatophore in Arenicola and a Theory of the Alternation of Generations suggested by the Facts in the Case. ELLIOT R DOWNING, Northern State Normal School, Marquette, Mich

The spermatophore in *Arenicola cristata* arises as a result of the cleavage of a primary spermatogonium in a manner homologous with the cleavage of an egg in the same species. There is an invagination of certain spermatogonial macromeres and micromeres to form the nutritive cells which supply the developing spermatophore with food by their disintegration and absorption These cells are homologues of the egg mesentomeres The spermatophore is shed from the testis into the body fluid at an early stage, sometimes even before the cleavage of the spermatogonium has begun Here the early spermatophore becomes a hollow mass of cells which later, by a false invagination, becomes gastrula-like. The false gastrula flattens out and becomes a saucer-shaped mass of spermatids. These develop within themselves the sperm.

The facts suggest that the spermatophore is an individual—the gametozoon which bears the gametes The adult male is a sporozoon which develops the spores or primary spermatogonia

The alternation of generations and reduction are independent phenomena, as is shown (1) by apogamy and apospory, (2) by the fact that among the protozoa and algæ reduction may occur before, during or after the conjugation of the gametes, that is, in either the sporo- or gameto-generation

Reduction is an adjunct rather than a corollary of sexuality If it were the latter, reduction should always occur in a definite relation to the sexual act, not before, during or after it

The spermatophore must be suggestive of the primitive animal type just as the gametophyte suggests a thalline ancestry for plants Perhaps the Volvocales come nearest, among living forms, the primitive form In *Volvox* reduction has its animal position during gametogenesis

If reduction occurred in the primitive forms before or during the fusion of the gametes the gameto- and sporo-generations would have the same number of chromosomes This is the case in the gametozoon and sporozoon of *Arenicola* Since all animals and many algæ have reduction in such a position the preponderance of evidence is that it had this position in the common animal and plant prototype In plants, then, it has shifted from this primitive place toward the end of the sporophyte generation

Aquatic Photography for Zoologists WM ALANSON BRYAN, Honolulu, H. I.

The paper briefly explains and illustrates with lantern slides some of the essentials in the method and the apparatus used in securing photographs of aquatic objects for book and class room illustration The successive steps in evolving a method that resulted in securing the first aquatic motion pictures are explained

The Discovery of Archigetes in America, with a Discussion of its Structures and Affinities: HENRY B. WARD, University of Illinois.

Among the monozoic cestodes, often grouped as a separate class or subclass under the name Cestodaria, the Caryophyllæidæ stand closest to the merozoic cestodes, particularly to the Bothriocephalidæ. Neither of the genera previously known, *Caryophyllæus* or *Archigetes*, has been reported from this continent, although several

species are relatively common in Europe. During the past summer, a form belonging to this group was found in fish from the Illinois River at Havana. Its structure shows certain features which are common to both of the known genera, *Caryophyllæus* and *Archigetes*. It resembles the former in the absence of a caudal appendage and in the location chosen by the adult parasite, viz., the intestine of a fish, whereas, so far as known in Europe, *Archigetes* always possesses a tail and has been found only in the body cavity of tubificid worms. In general appearance and structure the American form resembles the European *Archigetes* very strongly. It has a scolex of fixed form with primitive suckers or phyllidia and also the musculature of *Archigetes*. The general arrangement of reproductive organs, especially the two rows of testes in the central field, and the genital pores, correspond also closely to conditions in *Archigetes*. Two alternative hypotheses present themselves: (1) the European forms may have a yet undiscovered adult stage in some vertebrate host and in that case the caudal appendage would be lost as in *Caryophyllæus* and in the form under discussion, (2) the American form described here may represent a higher stage of development. In the latter case the European form is either a degenerate type in which the intestinal stage has fallen out of the life history, leaving only a sexually mature larva parasitic in the body cavity, as *Amphilina* another cestodarian has been interpreted by Pintner, or the American form indicates the adaptation by which the invertebrate parasite has acquired a vertebrate host and includes in its life history two hosts, as is typical in cestodes generally. The full paper will be published elsewhere.

Notes on Batinot Amphibia: ROY L. MOODIE, University of Kansas.

Chromosome Individuality: C. E. MCCLUNG, University of Kansas.

The Histogenesis of the "Transient" (Rohon-Beard) Cells in Selachian Embryos: H. V. NEAL, Knox College.

The study of the histogenesis of the "transient" (Rohon Beard) cells in selachian embryos confirms earlier conclusions based upon the study of the histogenesis of ventral nerves that the neuraxon process develops as an amœboid outflow of the neuroblast cell. The growth and histogenesis of the neuraxon process of the "transient" or "giant" cells of Rohon Beard may be easily followed, since in reaching its peripheral termination the process grows into and through spaces devoid both of mesenchyma cells and of intercellular bridges or "plasmodesmata." Such spaces, however, are filled with a plasma containing a slight amount of coagulable substance which with some fixing reagents gives the plasma a vacuolated structure. The termination of the nerve fiber or neuraxon, as it penetrates these spaces, consists of many pseudopodia like extensions. In some cases, as the neuraxon in its growth reaches the dorsal apex of the myotome, pseudopodial processes extend, some median and some lateral to the myotome. It seems to be a matter of chance whether in its further extension the neuraxon process shall grow median or whether it shall grow lateral to the myotome. Of a primary reticulum or "plasmodesma" connecting the neuroblast cell in the neural tube with its terminal organ there is not the slightest evidence. The experimental results of Harrison on amphibian embryos are fully corroborated by the evidence presented by the growth of the neuraxon processes of these "giant" cells.

Such facts obviously have an important bearing on the problem of the phylogeny of the vertebrate head, since they tend to disprove the assumption of earlier morphologists that nerve and muscle are inseparably connected and to make explicable the greatly modified metameric relations of the eye muscle nerves and possibly to give us the clue which may lead to the solution of the mystery of the chiasma of the trochlearis.

The Origin of the Rudiments of the Mesenteron in the Honey Bee: JAMES A. NELSON, Bureau of Entomology, Washington, D. C.

The anterior mesenteron rudiment of the honey bee arises at a period immediately after the appearance of the lateral folds, on the ventral surface of the egg near its anterior pole. It is at first nearly circular in outline, and sharply distinguished from the blastoderm by the deeper staining properties of its cells. At first it lies outside the area embraced by the lateral folds, but is later included in this area as the folds lengthen. Sections show that this mesenteron rudiment is produced by active proliferation of the cells of the blastoderm. After the union of the lateral folds this is detached from the blastoderm as a flat plate of cells which increases rapidly in extent, moves cephalad and soon covers the yolk at the anterior pole of the egg like a cap. The history of the posterior mesenteron rudiment is similar, but it is smaller, and first appears at the posterior pole of the egg. Later, after the rudiments of the appendages have ap-

peared, the stomodæal and proctodæal invaginations are formed at or near the places of formation of the mesenteron rudiments. The rudiments of the mesenteron at their inception are thus sharply marked off from the blastoderm of the middle plate (mesoderm) on the one hand, and the epithelium of the proctodæum and stomodæum (ectoderm) on the other These observations are in close accord with those of Carrière and Bürger on *Chalicodoma*

The so called blastopore and the yolk plug described by Dickel (1904) for the honey bee have been observed, but the writer can not confirm this investigator's conclusions relative to these structures The yolk plug, which Dickel thought connected with the formation of the mesenteron, was found in the same sagittal section with the true anterior mesenteron rudiment, the one on the dorsal, the other on the ventral surface of the egg, thus demonstrating that no close genetic relationship exists between them. The origin and fate of this so called yolk plug is obscure, but it is a transitory structure, of very brief duration, possibly a vestigial organ.

Birds of the Olympic Peninsula. ALBERT B REAGAN, U S. Indian Service

The Olympic Peninsula, Washington, extends from Grays Harbor on the Pacific coast north to the Strait of Juan de Fuca and east to the "sound" So far as the habitation of birds is concerned, the region divides itself into three parts—the coast strip, the mountains and the islands off the coast

The coastal strip ranges from twelve to thirty miles in width. The central, high section is a circular area forty miles in circumference in the east central part of the peninsula, ranging from 6,000 to 8,000 feet in height, with a declining ridge extending northwestward to Cape Flattery The whole mainland area, except in the high mountain districts, is heavily forested and covered with a dense underbrush so that near the coast it approaches the jungle state For this reason birds in this division are hard to find, as they can so easily seclude themselves, but at the beach line and in the island districts they are in evidence.

The land species generally met with are north western crow (*Corvus caurinus*), northern raven (*C corax principalis*), desert sparrow hawk (*Falco sparverius phalæna*), black cloud swift (*Cypseloides niger borealis*), American crossbill (*Loxia curvirostra minor*), Audubon warbler (*Dendroica auduboni*), rough-winged swallow (*Stelgidopteryx serripennis*), rufous hummer (*Selasphorus rufus*), rusty song sparrow (*Melospiza cinera morphna*), sooty song sparrow (*Passerella iliaca* (*fuliginosa*)), bald eagle (*Haliæetus leucocephalus*), black merlin (*Falco columbarius suckleyi*), Peale falcon (*Falco peregrinus pealei*), harlequin duck (*Histrionicus histrionicus*), ruddy turnstone (*Arenaria morinella*), Hudsonian curlew (*Numenius hudsonicus*), northern phalarope (*Phalaropus lobatus*), barn swallow (*Hirundo erythrogaster*), western winter wren (*Olbiorchilus hiemalis pacificus*), pectoral sandpiper (*Actodromas maculata*), western sandpiper (*Ereunetes occidentalis*), lutescent warbler (*Helminthophila celata lutescens*), russet backed thrush (*Hylocichla ustulata*), yellow warbler (*Dendroica æstiva*), black turnstone (*Arenaria melanocephala*), semi-palated plover (*Ægialitis semipalmata*), knot (*Tringa canutus*), wandering tatler (*Heteractitis incanus*), yellow legs (*Totanus flavipes*), also several species of ducks and geese (in migration)

It is the writer's opinion that there are 25,000 land birds in the peninsula

The islands are principally on the Pacific side and there parallel with the coast, extending from the mainland only a few miles seaward at most They number something like 100 points, rocks, pillars and islands proper. By position, they naturally divide themselves into three groups These groups were each made a bird reserve by President Theodore Roosevelt and designated as follows Copalis Rock Reserve, near Granville (Tahola), thirty miles north of Grays Harbor; the Quillayute Needles Reserve, in the vicinity of LaPush, Washington, and the Flattery Rock Reserve, including all the rocks and islands from the Ozette Indian village to the entrance of the Strait of Fuca.

These islands fairly swarm with birds The species most commonly observed are western gull (*Larus occidentalis*), glaucus winged gull (*L glaucescens*), Heerman gull (*L. Heermani*), marbled murrlet (*Brachyramphus marmoratus*),[1] California murre (*Uria troile californica*), black oyster catcher (*Hæmatopus bachmani*), loon (*Gavia imber*),[1] white winged scoter (*Oidemia deglandi*),[1] tufted puffin (*Lunda cirrhata*), pigeon guillemot (*Cepphus columba*), dark-bodied shearwater (*Puffinus griseus*),[1] surf scoter (*Oidemia perspicillata*),[1] Cassin auklet (*Ptychoramphus aleuticus*), rhinoceros auklet (*Cerorhinca monocerata*), American scoter (*Oidemia americana*),[1]

[1] Migratory.

Keading petrel (*Oceanodroma kaedingi*), Brandt cormorant (*Phalacrocorax penicillatus*), white-crested cormorant (*P dilophus cincinatus*), Baird cormorant (*P pelagicus resplendens*), western grebe (*Æchmophorus occidentalis*),[3] Holboell grebe (*Colymbus holboellii*) [3]

It has been estimated that the birds of the island groups, including the migratory birds, number at least 100,000

One hundred and thirty-seven species of birds have been listed from the Olympic Peninsula, and are described in the paper of which this is an abstract

The full paper will probably appear in the *Transactions of the Kansas Academy of Science.*

The Differentiation of Neuroblasts in Artificial Culture Media M L SHOREY, Milwaukee-Downer College.

The experiments to be described were conducted for the purpose of gaining evidence regarding the factors involved in the differentiation of neuroblasts Previous experimental work has led to the expression of two radically opposed views, one that they are entirely self-differentiating (Harrison, 1907, Braus, 1906), the other that no differentiation occurs except in the presence of the normal end-organs, or the products of the metabolism of these organs (Shorey, 1909).

Neuroblasts from the medullary canal of *Necturus* were placed in artificial culture media, one containing the products of muscular metabolism, and the other not In each the cells remained alive for a considerable period of time, but only in the first were fibers developed.

Spermatogenesis in the Mole Crickets. W. J. BAUMGARTNER, University of Kansas.

The paper will show the method of formation of the tetrads, and the method of maturation division The work indicates that while Vom Rath is correct in theory, his figures are not at all true to the conditions found in the specimens. His illustrations must have been drawn mostly from imagination

The chromosomes in the maturation divisions show a constancy of number, and a constancy of the series of shapes through which the individuals pass. The accessory is present, and one of the tetrads divides unequally

This paper will be printed in Kansas University Science Bulletin

SOCIETIES AND ACADEMIES

THE TORREY BOTANICAL CLUB

THE first meeting of the club for 1911 was held at the American Museum of Natural History, on January 10, President Rusby in the chair. Dr. C A Darling, of the department of botany, Columbia University, was nominated for membership

This being the annual meeting, reports were presented by the various officers

The report of the treasurer was presented and upon motion referred to an auditing committee

The secretary reported that fifteen meetings had been held during the year with a total attendance of 467, as against 411 in 1909, and an average attendance of thirty-one, as against twenty-seven last year Twelve persons have been elected to membership, and eight resignations received and accepted Six illustrated lectures were delivered during the season at which the combined attendance was 319, as against 251 at seven meetings last year

The editor reported that the *Bulletin* for the year 1910 contains 630 pages and 36 plates, and that the expense of its publication was less than the amount allowed for it by the budget committee He also reported that only one paper had been published in the *Memoirs*, this being a paper by Dr. O Butler on "The Californian Vine Disease" The editor declined to be considered for reelection

The editor of *Torreya* presented a special report for that periodical The volume of *Torreya* for 1910 contained 292 pages

The chairman of the field committee reported that twenty-three meetings were advertised during the year, one of which was an afternoon lecture at the New York Botanical Garden Eight meetings were not held on account of stormy weather or from other causes At the fourteen field meetings actually held there was a total of 103 persons present, making an average attendance of a little more than 7 at each meeting.

As chairman of the local flora committee, Dr. N. L. Britton gave a brief report of the investigations being carried on by Mr. Norman Taylor on the local flora.

Election of officers for the year 1911 resulted as follows:

President—H H Rusby

Vice-presidents—Edward S. Burgess and John Hendley Barnhart.

Secretary and Treasurer—Bernard O Dodge

Editor—Philip Dowell.

Associate Editors—John Hendley Barnhart, Jean Broadhurst, Ernest Dunbar Clark, Alexander William Evans, Tracy Elliot Hazen, Marshall Avery Howe, Herbert Maule Richards and Norman Taylor

The following committees were appointed by the president for the year 1911

Finance Committee—John I Kane and H M Richards

Program Committee—Elizabeth G Britton, Fred J Seaver, Tracy E Hazen and Jean Broadhurst

Field Committee—E B Southwick, Norman Taylor and William Mansfield

Committee on Local Flora—N L Britton, chairman, Phanerogams N L Britton, C C Curtis, E P Bicknell, K K Mackenzie, E S Burgess and E L Morris Cryptogams Wm A Murrill, E G Britton, Tracy E Hazen, M A Howe and Philip Dowell

Budget Committee—H H Rusby, E S Burgess, J H Barnhart, B O Dodge, Philip Dowell and N L Britton

PERCY WILSON,
Secretary

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

THE 450th regular meeting of the society was held in the hall of the Public Library, December 20, 1910, 8 P M., with the president, Dr J Walter Fewkes, in the chair

The paper of the evening was on "The Winnebago Winter Feast," by Mr. Paul Radin The speaker gave a description of the ceremonies incident to this feast and dwelt on the religious and social elements connected with the celebration

In the discussion, which followed the reading of the paper, Dr Swanton stated that among the Indians of the Pacific coast the ceremony is observed on the death of an uncle and to strengthen a chief, but in either case the social element predominates over the religious Mr La Flesche pointed out that among the old tribes the feasts are held about spring time, when life is awakened, heralded by the arrival of thunder Mr Hewitt and Dr Fewkes gave parallels from the Iroquois and the Hopi Indians, respectively.

THE 451st regular meeting of the society was held in the hall of the Public Library, January 17, 1911, with the president, Dr J Walter Fewkes, in the chair

The first paper of the evening was on "The Totemic Complex," by Dr A A. Goldenweiser. The speaker first gave a brief survey of the study of totemism from the sixteenth century to the present as represented by Frazer, Morgan, Lang, etc, in England, and by Boas and Swanton in America He then pointed out the difference of conception and method between the British and American investigators and subjected the English point of view to a thoroughgoing criticism This point of view is evolutionary and comparative It assumes totemism as a necessary stage in the evolution of religion and hence wherever it could trace the existence of one of the supposed elements of totemism, such as exogamy, tabu or totemic names, it established there the existence of the totemic system In this way totemism was attributed to the ancient Egyptians, the Romans, the Semites (by Robertson Smith) Dr Goldenweiser pointed out that the various features of totemism, such as exogamy, tabu and descent from an animal are nowhere found united, but exist separately and independently from one another and are hence not correlated to one another Totemism can, therefore, not be studied as an organic whole, but in its various elements The element of descent is the main feature which gives a social coherence and stability to a social group Next to this in importance is the bond of union formed by common ceremonies

The second paper was on "The Medicine Arrows of the Cheyenne," by Dr Truman Michelson The ceremony, which was attended by the speaker in 1908, consists of a long ritual, songs and prayers, and lasts through seven days. Of these the first three days are preliminary The persons taking part in the ceremony are the chief priest, the candidate or candidates who are to be initiated, each accompanied by a friend who acts the "old man" The participants live during the seven days in lodges or tents within a closed precinct The speaker recited parts of the songs and prayers addressed to sky and earth These are accompanied by processions, moving from lodge to lodge, burning of pieces of sweet grass, etc The center of the ceremony, which gives it its name, consists in laying arrows on the ground, with heads to north, surrounded by twelve buffalo heads The officiating priest goes through various motions, while the candidate breathes four times on the arrows. No woman may witness the ceremony.

Both papers were discussed by Messrs Swanton, Hewitt, Hough, Fewkes and Casanowicz

I. M. CASANOWICZ,
Secretary

BACTERIOLOGY IN GENERAL EDUCATION[1]

IN casting about for a topic around which might be gathered a few thoughts suitable for this occasion, I was impressed with the lack of appreciation of the value of bacteriology in general education and the comparatively small amount of systematic effort that has been put forth to establish efficient methods for teaching this important new science. I became so deeply interested in these phases of the subject that perhaps with more zeal than wisdom I chose for my topic "Bacteriology in General Education."

The practical value of any branch of science keeps pace with the general knowledge of it and an understanding of the methods by which it can be applied. This in turn depends largely upon the teaching of those who are versed in its details of fact and law. The earlier recognition of bacteria did not suggest the important rôle they play in nature's economy. While their existence had been known for more than two centuries, it was not until their causal relation to infectious diseases was recorded that they made an impression upon society in general, and the medical profession in particular. It was the discovery of this great power which they possess to destroy man and beast that afforded a point of contact between humanity and this vast, invisible, organic world about us. If I correctly understand the meaning of our declaration in the constitution of this society, that its object is the promotion of the science of bacteriology, it would seem

[1] Presidential address delivered before the Society of American Bacteriologists, Ithaca, N. Y., December 28, 1910.

that our first and most sacred duty is to ascertain the facts in the life history of microorganisms, to describe the laws governing them and to bring this knowledge into bold relief, in order that so far as possible it may be utilized for the benefit of humanity.

It is often the tendency of men who spend their lives in the seclusion of scientific research to become less mindful of the possible practical application of their work than they are of the technical details and of the truth which it reveals. This is of necessity a natural tendency, for application can not go in advance of the discovery of the facts to be applied. History is replete with illustrations of unsuccessful efforts to benefit humanity by applying theory or dogma in the place of knowledge which perhaps at the time did not exist. On the other hand, the results of investigations of the men of pure science have often led to the formulation of exceedingly practical procedures. In the development of the theory and of the application of a science, therefore, we have to deal with two factors, namely, the intellectual longing for truth regardless of its immediate significance, and the desire to apply specific knowledge for the benefit of society. Occasionally these two elements are equally marked in the same individual. As an example of a mind dominated by the experimental method, as well as the desire to alleviate the suffering and to improve the life conditions of mankind, there is no name that can be mentioned with greater fitness than that of Louis Pasteur, the founder of bacteriology as a practical science.

Almost from its inception, bacteriology has been a technical subject with important practical applications. It has been the agent that has revolutionized the medical professions, vegetable pathology, dairying and soil economics. The bacteriological work that is being done at the present time is for the most part aimed directly at some one or other of the problems in these practical fields. There are few sciences in which the newly discovered facts or laws have been so quickly utilized for some real or hoped-for benefit to man or beast, as in microbiology. The result of this haste to apply new theories has tended to confuse the public relative to the possibilities of a knowledge of microorganisms. It is difficult to have the truth crystallized that bacteriology is a technical subject which can be understood by the specialist only. The tendency to immediately apply newly cited facts, before they are properly demonstrated, has not infrequently permitted errors to be proclaimed as truth, with ultimate disappointment for both those looking for beneficial results and those attempting to attain them by the use of methods based on somewhat hypothetical data.

This is illustrated by the present confusion relative to the various groups of bacteria. The discovery of the tubercle bacillus was followed by the declaration that it was the same in all mammalian tuberculosis. This assumption was applied in the prophylactics of tuberculosis before the important fact was ascertained that there are varieties or races of tubercle bacilli, and also that there exists a large group of bacteria morphologically and micro-chemically at least related to them. Laymen and even medical men are having difficulty to reconcile more recent findings with the original teaching relative to the identity of mammalian tubercle bacteria. I do not refer to this disparagingly, for progress is sometimes made by retreats as well as by advances, but could the truth concerning the tubercle group of bacteria have been determined before the application of the hypothesis that the etiological

factors of human and bovine tuberculosis were identical, much controversy would have been avoided and numerous sacrifices and hardships would have been saved. I have called attention to but one of the important subjects in which the earlier positive statements have been greatly modified by later discoveries, for the purpose of emphasizing both the difficulties and the responsibilities of the bacteriologist in developing a pure science and in applying it in a practical manner.

From the earliest times, life has been given the highest price in the rôle of earthly possessions. How to prolong life has been the theme of many. In more recent years, economists have considered at length the cost to the state resulting from immature death and for maintenance of its sick and diseased citizens. The country is spending millions of dollars annually to support hospitals and asylums for the incurables. As Messenger has stated it, such a work is greatly to the credit of our hearts but not so much to the credit of our heads. Society has been temporizing with these great vital and economic questions, for the aim of the future is to restrict the need for hospitals by preventing disease. The nation-wide conservation movement has a large task to prevent the damages wrought in nature's economy by microorganisms. Again the state and society are calling upon the bacteriologists to bring to the pressing needs of to-day a knowledge of the vital forces that will tend to purify polluted streams and make the soil more fertile. The prevention of infectious diseases and the conservation of the soil are two great tasks that confront practical bacteriologists. The question is: How, in the present demand for applied bacteriology, can this science attain to its highest development and at the same time render the greatest service? The declaration in our constitution limits our field to the promotion of the science of bacteriology, while other organizations have largely for their duty its utilization. It is practically impossible to make this differentiation complete, for as yet there are no societies that seem to deal with the application of important recent bacteriological findings. It is clear, however, that the essential purpose of this organization is to safeguard the purity of the science and to point out the way for its advancement.

The fact has already been conceded that bacteriology is the science that has much to do, and in certain instances practically all to do, in finding the solution and in settling the details of many of the common every-day problems in the conservation of life and health of the higher forms of life. Yet this science, with such possibilities, possesses scarcely any interpreters of its actual value to society at large, and it finds little or no place in the curriculums of our schools and colleges for general education.

The true significance of a knowledge of bacteriology should require no explanation. Because it has grown up through technical laboratory research and routine, educators seem to feel that its true service is restricted to such laboratories. For the highly specialized or professional work we agree, but should not the knowledge of basic facts and natural laws that have transformed so many practises in medicine, sanitary science and agriculture become common property? Is there not a place in our common schools and liberal arts colleges for courses in bacteriology for the purpose of imparting fundamental knowledge that will enable society to come into possession of an understanding of this science? It can not be successfully gainsaid that information concerning the cause of fermentations, the storing of nitrogen in the soil, the causes for the changes in food stuffs

and the etiology of the common infectious diseases is as important, or the acquisition of such knowledge of as much disciplinary value, as the study of the life history of the denizens of the deep as now required in many if not most biological courses The world looked with wonderment at the hitherto unparalleled success in avoiding preventable diseases by the Japanese army at the time of the Russo-Japanese war Up to this conflict it is affirmed that for every man killed with a bullet in war four died from infection, while in the Japanese army for every man who died from infection four were killed with bullets The explanation of this victory over all the experience of the past was found to be the training of the Japanese soldiers in the principles of bacteriology It should be clearly understood that this marvelous success was due simply to the application of knowledge which Europe and America had brought forth and which the Japanese had applied Would it not be quite as valuable in civil life to have the people versed in the simple facts and principles of a science that would enable them intelligently and designedly to avoid infection, strengthen the efforts of the sanitarian, and enable the agriculturist to restore fertility to the soil, as to have them possessed of a knowledge of things far remote from their immediate environment? It is not my desire to belittle any course of instruction, for all knowledge is valuable, but I do wish to record the opinion that a science like bacteriology, which plays such an important part in the immediate physical well-being of every individual, should have a place in the curriculum of the schools for the masses

Because bacteriology is a technical subject with numerous avenues of usefulness there is the greater need, in order to prevent errors in its adaptation, for efficient instruction concerning it in both popular and technical schools The prevention of its false application will attain its maximum success after the diffusion of knowledge concerning microorganisms Knowledge is power, and when the people are versed in the fundamental principles of this science they will avail themselves of such information to improve their condition economically and to avoid the dangers of infection

The position occupied by bacteriology in general education will depend largely upon its teachers At the present time it has not been granted, with few exceptions, a place in the curriculums of popular educational institutions Sanitarians and others have endeavored to educate the people in its principles by imparting isolated facts This is having a certain beneficial effect, but unfortunately the recipients are unable to adapt this fragmentary knowledge to new conditions At present the masses depend for their guidance in this subject upon the results obtained in professional laboratories and the teaching in technical schools As bacteriology had its origin in the findings of those seeking the cause of important phenomena, it is to be expected that, for a time at least, its fountain head will continue to be in the results forthcoming from such researches As these investigators are largely its teachers, we are brought to a discussion of methods for teaching it in professional schools

I am led to touch upon this subject from the point of view of students, as I have known them, who have received their elementary training in bacteriology in different places Every one who has to deal with post-graduates in this subject appreciates fully the difficulties encountered in properly orienting the subject-matter taught to beginners in order to produce the desired

result. It is the presence of these difficulties that prompted the opening of this subject, which can not be closed until after the results of many trials and careful discussions are recorded. On my shelf are numerous text-books and laboratory manuals for teaching this science. If they are carefully analyzed, they will give a variety of impressions as to the purpose of the course prescribed. Here then is found the logical reason for the discussion of the fundamental principle in its teaching. The crux of the question is: Shall bacteriology be taught as a science in our professional schools or shall simply the essential facts to be applied be imparted?

Some years ago I accepted a position carrying with it the responsibility of teaching bacteriology in a professional course. I went from a research laboratory where I had grown up with the technique and knowledge of a certain phase of the subject. I labored under the delusion that the essential elements could be easily taught. There was no difficulty in securing the interest of the students, but the pangs of disappointment were mine when these same interested men attempted to apply the knowledge I supposed they possessed, in the actual practise of their profession. Their errors were not more grievous than those of other men, but the things they did and the kind of assistance they sought pointed clearly to a lack of knowledge or understanding of the subject which I believed I had taught with great clearness. This combined experience has caused me to question the efficiency of many pedagogical methods employed in teaching bacteriology, and to test as best I could different methods of instruction. The conclusion that seems to me inevitable is that the course in bacteriology must be dominated by a scientific system of presentation and that the technique, facts and laws of bacteriology must be clearly developed before too much stress can be placed upon the value of fragmentary facts such as staining tubercle bacilli, or the examination of water for the colon bacillus. The difficulty does not rest alone in a lack of the knowledge of technique in making the examinations, but quite as much in the inability to interpret the findings. Conclusions drawn from isolated facts by partially informed individuals are responsible for many of the charges of error against our laboratories. There is, therefore, no way to more effectively promote this science than to have its conclusions based on accurate and verified data.

I have considered the difficulties encountered by way of lack of time granted to bacteriology in curriculums, the eagerness of many inexperienced men to assume charge of bacteriological work and the pittance of salaries often paid for this service. These are recognized hindrances, but they are far more easily overcome than the results of hurried application, snap diagnosis, indifference and commercialism that dominate this work wherever the spirit of science and regard for scientific verification are not enthroned. If the public is to be benefited, as it should be, by the existence of this science, it is important that those responsible for the training of men to occupy positions in public laboratories take fully into account the nature of their teaching. Wherever the true scientific spirit dominates the final results prove to be more helpful. It is not my purpose, nor do I believe it possible, to outline a schedule to be followed by all. It is, however, within our power to give to bacteriology the dignity commensurate with its vital relations to our environment and to teach it as a science and not as an aggregation of biological facts.

I can not leave this subject without

pointing to the possibility of misguided application of this science because of a lack of understanding of it The mere knowledge of the presence of microorganisms in milk, in water and in dust is responsible for many unprofitable propaganda In following these, the real dangers may be overlooked This is illustrated in certain practises There are, for example, those who, because of a low bacterial count of milk, consider it of excellent quality, without taking into account the condition of the udders or the general health of the cows from which it was obtained In certain lines of domestic science much stress is placed on the bacterial content of dust and the unsanitary condition their presence creates, when the actual problem is simply one of cleanliness, as the organisms present are of less significance than the dust itself Regulations based on certain microbian findings and the importance thereof are frequently appealed from because of the seemingly unwarranted expenditures they impose. Many of these interpretations prove later to be without justification, and the annoyance and perhaps hardships they occasioned would have been avoided if the science of bacteriology rather than a few isolated facts had been applied

There is at present a great demand for men who are capable and qualified to bring to the aid of those struggling with great sanitary and economic problems the relief that is possible, or that seems to be attainable by the utilization of the laws of microbiology The question we have to consider is how this demand can be satisfactorily met How under the present restrictions of bacteriology in technical schools and the willingness—because of the lack of knowledge of it—to keep it out of curriculums of schools of liberal arts and sciences, are we going to secure the men and train them to efficiently occupy these positions? The answer may come that our problem does not differ from that existing in other biological and physical sciences This may be true, but the fact remains that we are a body organized to promote this science and consequently clothed with responsibility that we can not throw off relative to the ways and means to be employed in bringing into existence more efficient bacteriology The lesson taught by the older branches of knowledge, such as chemistry and physics, points to but one solution, namely, the upbuilding of the purity of the science

Thus far, bacteriology has operated as an aid to many branches of applied learning, like medicine and agriculture, and for that reason it has not reached its full development as an independent science Because of this its greatest value has not been secured by those activities which it has served Its application has been so immediate that most of those who have come in possession of any knowledge of it have been attracted to some field for its application Some of these places require more breadth of knowledge than others, but there are indeed few of them where bacteriology is dignified as a pure science and its truths and laws studied, tested and cherished as such. The difficulties met in nomenclature, bacterial floras and technique speak for themselves concerning the fragmentary status of the knowledge of this subject With its diversion to practical lines there is too much specialization before there is a foundation of basic knowledge sufficient to support the superstructure. The desire for application rather than the scientific spirit is manifested too early and often too conspicuously in the devotees of this subject.

Perhaps the greatest difficulty in finding men desirous of taking up bacteriology for a life work is the fact that it is an un-

known topic to them until they reach it in some technical or professional course By this time their mind is usually centered on the line of attainment desired, and the hurried instruction they receive in bacteriology does not illuminate the science sufficiently to attract them To overcome this, two alternatives present themselves, namely, to have a preliminary course in bacteriology in the preparatory school or to have the course in the professional schools extended and taught more efficiently It seems to me that it is a mistake to assume that persons who have received instruction in some narrow field of the subject, and who may decide to follow this work, are qualified to take at once positions of responsibility There is no other science where accuracy, correct interpretation and application are of more vital importance than they are in this, yet there is no other science where men are elevated to positions of responsibility with so little real preparation We seem to have forgotten that in the acquisition of knowledge and the coming into an understanding of bacteriology the element of time and the discipline of routine work and research are as essential as they are in chemistry or in physics Again, in the preparation we must not be unmindful of the necessity of a thorough preliminary training in the fundamental sciences and modern languages

The question is a perplexing one The errors of insufficiently trained workers call forth trying criticisms that those who are responsible for laboratory work must bear Yet when more thoroughly qualified men are sought for they can not be found What then are we to do? We each and all who are in professional schools must feel that the regular course or courses we give in bacteriology can not fully or adequately prepare one for teaching the subject or taking a responsible position in it Yet the student has ability, is earnest and a hard worker He is financially so situated at the time of his graduation that he can not continue his studies In this condition the acceptance of the proffered position, with the mental resolution that he will study hard and later do graduate work, is apparently the thing for him to do The outcome of such a course is well known The numerous and unexpected difficulties attending the new position together with the increased amount of routine exhaust the energies and the hoped-for special training is rarely secured and the desired efficiency is not attained Until we have a better system for preparing young men the present practise will continue and our science, our laboratories and the public must suffer the consequences

I have dwelt somewhat at length on the difficulties which exist in the promotion of the science of bacteriology If they are analyzed it will be found that they are temporary, and incident to the way by which man found his dependence upon his microbian environment After the numerous demands for men to do work, which the recognition of the importance of microbes has created, bacteriology will undoubtedly develop into a pure science that will be as eagerly pursued as any branch of learning in the acquisition of an efficient education.

In conclusion, I desire to make a few suggestions as to the possible means for both promoting this science as such and increasing its value as an asset in practical knowledge.

The first is to introduce in the courses of biology in our common schools, instruction on the existence and varieties of bacteria, and something of the action of a few of the more important economic species This would afford a little fundamental knowledge to help the masses to better understand the cause of many natural phenomena.

The second is that there should be established in our normal schools, colleges and universities thoroughly scientific courses in bacteriology. Such a course would lay the foundation of the science and place it on a par with other branches of biology, such as botany and zoology. Such departments should be prepared to do research, thereby fitting men for the special phases of the subject in technical and professional schools, and qualifying others to do research of a purely scientific nature, without reference to any particular trade, occupation or profession. The problems here are as numerous and their solutions are as taxing upon the mental forces of the investigator as they are in any branch of scientific endeavor.

The third suggestion is a plea for more scientific methods of teaching bacteriology in our professional schools. The course should, as a rule, be lengthened and the theoretical teaching supplemented by as much practical work as possible.

We should in view of all conditions rejoice in the achievements of the first half century of practical bacteriology. There is every reason to believe that with a better understanding of the vital relation of the microbian environment to higher forms of life bacteriology will be productive of still greater benefits, because of the education of the public concerning it and because of its more intelligent application by all.

VERANUS A. MOORE
CORNELL UNIVERSITY

THE PALEONTOLOGICAL SOCIETY[1]
ADDRESS OF THE PRESIDENT

THERE is a respectable virtue in the observance of well-tried usages. In the societies out of which we have emerged it has been the established procedure to penalize a retiring president with a somewhat formal address. It is a practise which is at once a solace and an opportunity, the former, inasmuch as successors to this honor of office must share these heart-searching efforts of its closing hours, an opportunity, for here is an outlet to unspoken cogitations which seldom take on the formal expression of the printed page, a chance to weave together the threads of evidence or suggestion we may have followed many years and left dangling, perhaps even, to perfect into some well-finished form the summation of our larger problems. It seems to have been tacitly assumed by our council and membership that I should inaugurate for this society the accustomed procedure anew. I frankly face this situation, but with no promise of the adequacy of the outcome.

I. At the outset I propose to take brief advantage of my own somewhat peculiar position and experience as a public official in paleontological science as a point of view from which but few of you, my audience, may have had opportunity to contemplate the subject. You will, I pray, be indulgent with this exploitation of a personal attitude, for it does seem to have certain complementary attributes which may in a way illuminate and supplement your own experience. If you find it a rather frank expression it will be couched in terms of fraternal regard, and I hope entirely devoid of unfair or invidious comment which might expose the writer to the charge of being a profane railer at the sanctities. My contact with the public of an intelligent and progressive government is now of rather long standing and this experience has been illuminating in any estimate of public sympathy with pure science.

[1] Delivered by request at a joint meeting of this society and the Geological Society of America, Pittsburgh meeting, 1910.

It is safe to say that most of you are doing your work in the atmosphere of academic vales and cloisters where the prosecution of pure science is an elemental virtue. The very air you breathe is an inspiration to pursue any esoteric cult to any limit, howsoever far it may shape its course away from any apparent direct bearing on human happiness. An enlargement of human knowledge, even though already enlarged beyond human power to grasp, and the possibility of enlarging the comfort and hopes of mankind are justification for this pursuit, if justification be called for. Happily it is not needed, for the very next step, the scientific fact that lies unturned at our feet or the discovery just round the corner, may be as essential to philosophy and to progress as all that have passed by in their countless array. At your command is all that is best in the sciences and among your academic fellows in towns well oxygenated by the very air you exhale, you attain to the full measure of useful citizens. It might be trite for me to say that glorified with a splendid growth in the conservatory atmosphere of the university, the professor of science strays abroad from penetralia of his divinities with an acquired confidence of superiority, into a hardier air and a coarser grained world which declines to take him at his own valuation. I am disposed to think the sheltered aisles of great federal bureaus afford a very like protection from the assaults of the so-called practical community.

But take a man of pure science, and stand him out in the open where he must come into daily contact with men of affairs, men who are making a noise and doing that part of the world's work which feeds upon publicity, with the pulverizing wheels of political machinery and with the commercial sentiment which dominates to-day more than ever before nearly every phase of government and nearly every aspect of society, and if he fails to take his own measure of so-called "practical" usefulness to his community of city or state, it is taken for him. If he can stand the shadowless glare of such an attitude he realizes at length that he is not indeed as other people are. By devotion to the duty his science imposes he may merit the confidence of his sponsors, but he is not likely to become the director of a bank or be invited to sit as a member of important fiduciary or social trusts. He is, in plain truth, quite generally regarded in the community as a rather unproductive if not visionary member of society with a large supply of useless knowledge but with a very limited capacity for making dollars, not always immaculate in his attire or particularly well groomed in person, somewhat terrifying socially, though harmless, perhaps, in his honest effort to turn a rather unintelligible hobby into the means of a livelihood. This expression is not, I think, an unfair phrasing of the general public attitude in our communities toward, not the man of pure science alone, but all high scholastic attainment. Notwithstanding the intellectual regeneration beginning with the last half of the last century which has tended to place all lines of human thought on a scientific basis, our best communities are still largely thinking deductively, and the rest entirely so whenever their thoughts have time to reach beyond their income; and we too may indeed confess freely and without shame even in this presence that something more of the prophet's vision, of the philosopher's method and of the poet's inspiration is stealing back into our own intellectual modes. You and I, men who are giving our best years and skilled energies to the elucidation of the organic law, the higher

law which alike makes the flower bloom and the philosopher think, the one law which governs all the world save only human society, are reasonably content in our security that we have chosen the good part and we decline to subject our standards to those of the eminently companionable and high-minded citizenry of the communities in which it has pleased God to place us

Paleontology is, in my oft-asserted conviction, the most far-reaching of all the sciences In it lies the root of all truth, out of it must come the solution of the complex enigmas of human society Whatever it may be in the first instance, it is in the event that greatest study of mankind—man It is the panoramic display of the life of the ages, the expression of the organic law of a hundred successive worlds To quote the expression of Depéret it has won its independence and is now marching hand in hand with biology toward the discovery of the history of the development of living beings and the laws which control their transformations We unbar its doors and unlock its secrets only with the key of the present. To me it seems idle to fatuity to magnify the supposed imperfections in the record of life on the earths that have passed Such efforts are constantly recurring, and when taken out of their proper setting are the last resort of the theorist and the special pleader. The known fauna and flora of the living earth is a percentage of the actual fauna and flora, and only in less degree is the known life of the past since Azoic time to the actual life of that past The argument here has never been adequately presented, the facts never fairly marshalled, and we all too easily in our self confidence are wont to forget that after only a few brief years of study of the earth we still are standing at the threshold of the earth's history and with a few facts in our possession grow impatient to habilitate the earth, while its deeper chambers still conceal records reserved for our successors to uncover. In the long ages which lie before the human race must come through greater wealth of knowledge a clearer view and more fruitful application of the truth we seek To-day we begin to see the broad generalizations of the biologic law as based on paleontology which twenty years ago we believed so secure and illuminating, slowly yielding under the weight of accumulating evidence, and we should realize more deeply than ever and should, I believe, endeavor to leave the impress on our successors that it is still more knowledge that we require—it is still the facts we want, rather than the apparent inferences from those we have Were demonstration of the propriety of this attitude required, let me venture to cite, as an interested onlooker, the enormous volume of unpublished data bearing on the life of Cambrian time which has been brought together by the secretary of the Smithsonian, facts which when known and assimilated must modify nearly every published conception of the development of life on the early earth A few years ago at the opening of this century I ventured to address a personal letter to some ten men recognized as European leaders in geological work and thought, asking an expression as to what, in their judgment, would be the problems before the geologists of the coming generation The replies were all alike in essence and reducible to this: The acquisition of more facts. To-day we see only through a glass darkly into our cathedral where the truth lies enshrined

We know well enough, indeed it is a healthy sign that we are growing painfully conscious, that the standards of our best civilization are not those which have been

derived from a clear apprehension of the paramount law. We are certainly justified in our impatience with these standards so far as such impatience helps to make them or mankind better Whoever seriously contemplates the historical development of our culture standards out of a barbaric past can hardly fail of restiveness under them, whether of our educational system with its burden of time-worn incongruities and maladaptation to highly differentiated individualities, in which to the common scandal of the race our youth have been treated as papers of pins, machine-made watches, or as communities of ants, of our various religions "with their mossy heritage of half truth and half fiction," of commerce with its Midas dreams and cut-throat ethics But it is not likely that we can effect any perceptible influence upon these only as the pebbles of truth, brought together by the patient and persistent search which we pursue and encourage, cemented by the pervasive law of life, will some time make more secure the foundation for the superstructure of society Men of science are freely accused to-day of a *snobisme scientifique* The reproach comes pretty hard and fast from certain highly deductive quarters peopled largely by conventional thinkers And it is not always in French, either We may make all allowances for criticisms of our work based on a point of view quite inconceivable to consecutive inductive reasoning, but the fact is quite evident that scientific snobs and scientific snobbishness do abound A clergyman of my acquaintance asked a scientific friend about his work—what vast problems were now occupying his mind, and with utter and quite needless frankness the answer was—Repairing the conclusions I arrived at last year That quickly served to point a sermon on the errancy and frailty of inductive science. But while the clergyman and the type of thought he stands for ought to know that progress in knowledge is never along direct lines, always in bewildering zigzags and pulsations which nevertheless end further forward than where they started, still the man of science does himself and his work an injustice in permitting himself to be exploited by agencies of popularization which are in essence entirely hostile to his mode of thought So long as the whole pathway of science is bordered by the graves of cast-off theories and the atmosphere of to-day reeks with the aroma of new theories standing on probation and some in dire need ot burial, it is wholesome to stop and reflect that these in their turn are likely to be inhumed with only rotting stones to mark the names of their progenitors

We must recognize the fact that there is to-day a palpable reaction against the scientific mode for which we are ourselves to blame The uplifting impulse given to every department of thought by the revival of the last decades of the nineteenth century is followed in this decade by a tremendous rebound We may not all be fully conscious of this, as we are in some measure aloof from the pulse of other than scientific thought, but its proportions are well expressed by the formal and direct organization against the scientific mode embodied in such a masterly structure and so well-generaled an army as the eucharistic congress Let us not deceive ourselves, this great body of serious-minded deductive thinkers marshaled for no other purpose than to counteract the logical and the obvious and to encourage reliance on the mysterious is not standing alone. The ease with which we make and unmake hypotheses, the finality with which we enunciate propositions, the autocratic statement of possibilities as facts unques-

tionably tend to lead pure science into disfavor wherever the humanities are more prevalent. This unhappily growing disposition to finality of statement, forgetting that we are still watching only the first scene of our drama, is, I think, essentially at fault, and we are ourselves largely to blame for an evidently increasing indifference with which the autocratic theories of science are now received. Nothing fails in our philosophy, there is neither want of majesty or fullness of truth in our objective. But men of science need to mend their manners.

The vast majority of all our communities to-day are almost wholly abandoned to commercial pursuits. However this truth may be paraphrased, the euphemism of "making a living" applies to the absorbing share of human activities, instigates the volume of our legislation, controls our international relations, impregnates conceptions of the conservation of natural resources and lies at the base of all the comforts and conveniences of life which we now enjoy in unparalleled measure. Commerce has been the advance agent of civilization, has reduced the wilderness to an Hesperidean garden, is the seat and source of power of one over another, whether of individual, state or nation. To the advance of commerce both science and art are under tribute, but to the commercial spirit itself the human world owes no good thing, no higher thinking, no advance of vital truth, certainly no ethical progress. It is, like the lust of blood, a primitive impulse which still overpowers the race and it gives the reflecting man some notion of how short is the way he has traveled toward excellence and how long the road that lies ahead. "Science," says a recent writer, "means service." That is applied science in its relation to the state, and it is well. But "science" has a profounder philosophy and blessed it is for humanity that the scientific *ideal* is sometimes wholly supreme and the *achievement* wholly incidental.

Experience and observation have deeply impressed me with the conviction that the most subtle intellect in our communities is that of the lawyer. I use the term only in its broadest and best sense. Trained to precise and consecutive thinking, averse to conclusions without full substantiation in fact or precedent, dealing with, at the bar, but perhaps, abhorring from the bench, hypotheses and reasonable presumptions, skilled in holding judgment in reserve and averse to dogmatic statement, the very intellectual practises which have effected these traits have helped to evolve a mental machine of extraordinarily delicate caliber and accurate register.

I can conceive of no finer training for a scholar of pure science than a course in the precedents and procedure of the law, if not carried too far, or if not that at least such intimate personal association with members of the legal profession as will help to irrigate the method of the scientific man with the mental prudence and reserve of the lawyer. Such a training would be better than Greek. The body of men that constitute the tribunals and the advocates in any country are the most influential element in conserving its culture. They are an anchor to windward. For human society they perform a function comparable only to that of the conservative mother in humanity; they ensure the perpetuation of the type.

But the lawyer is a dead wall to the progress of scientific truth. Deference to the common law, allegiance to the statute law, seem to have developed in him, both by training and association of ideas into the essentials of an instinct. We will not assume that the shortcomings of the con-

venances of the statutes are not more evident to him than to any other intellectual class in the community, or that he is blind to the mere expediencies of most legislation. Decent regard for the historic corpus of the law which embodies the experiences of self-governing people is essential to our community existence, but among the lawyers I have known best there seems to be ever a really inadequate apprehension of the essence of the law as expressed in Froude's definition of the term. "Our human laws," says Froude, "are but the copies, more or less imperfect, of the eternal laws so far as we can read them, and either succeed or promote our welfare, or tend to bring confusion and disaster, according as the legislator's insight has detected the true principle or has been distorted by ignorance or selfishness."

In fact, the natural law finds as yet feeble expression in our statutes. Certainly its recognized bearings are becoming incorporated into the laws of this land only as these recognized factors protect or guarantee the material rights of the people. But it is clear that neither the bare fact of legislation nor the decisions of the courts rest on any adequate conception of the workings of the natural law. Deference therefore to the written statute on the part of those whose intellectual energy is devoted to its interpretation or its execution, seems to have well-nigh suffocated the purpose to grasp the higher law on which governments built to endure must be established. Pure science which concerns itself in the search for the actual law regardless of its bearings on the present constitution of society, finds amongst this class in the community toleration, indeed, but little sympathy.

Of the three so-called learned professions in our early communities, the "doctors" constituted one. They do yet. To them we owe a debt which can not be expressed. Their contributions to a knowledge of the biologic law are immense, far greater indeed than many of that profession realize. Speaking generally and broadly, it is fair to say that the physicians and surgeons of our community have worked out to approaching completeness the anatomy and functions of the most intricate and highly specialized member of the animal creation. It is probably true that, with brilliant exceptions, they have not often looked long or seriously into organic nature beyond or below man, nor sought the solution of his complicated morphology in its earlier expressions or in its history. No doctor of medicine or of human anatomy would have conceived a theory of natural selection or any other procedure of organic evolution. It was bound to come either from the student of pure biology or paleontology or from the poet. Starting at the top instead of the bottom of the ladder of life, by empirical methods fraught with immense consequence to humanity, they have solved many of the mysteries of life.

Concretely viewed, the appealing merit of their part in the revelation of the natural law lies in its contribution to human happiness by the relief of human misery but abstractly this application is of no concern in the philosophy of nature. The physical man is an item in the scheme of life and he would be audacious indeed who would say he was more. But it is the most compelling fact of existence that we are that item and it is our comfort and progress that has been and are to be largely ensured by these conservators of our being. We may smile with some degree of indulgence over this monopolistic trade-mark of doctor. You who have earned your doctorates in science or laws by long years of close application to arduous work will find

your achievement unrecognized by the doctor of medicine who acquired his degree by a three or possibly four years course in some medical school only possibly of respectable grade In the community, outside of the university circle, you will be addressed by them as Mister, preferably as Professor, and if the latter, with apparently no other distinction in mind than that you are of a peculiar social genus which for convenience and to avoid infringement of copyright is so designated and with broad enough application to embrace with you the dancing master, the friseur and the artist in fistics It is perhaps reasonably true that in any community deprived of the academic atmosphere, that is in the average American community, there is among practitioners of medicine and surgery an indifference to or failure to grasp the purport of pure biologic research, so complete and dense as to be appalling, the more as it lies in a quarter where one might most reasonably hope for support and sympathetic concern Compared with the intelligent manufacturer, the wholesale merchant, the banker, the stock broker, the modern farmer, the average physician or surgeon carries toward the ideals of our science and of geologic science as well, so far as the results involved are not strictly commercial, an air of indifference that partakes of the supercilious

These are the chief elements in our human atmosphere with which the work of some of us must most often come into close contact As for the two influential classes —the clergy and the teachers—taken together as one class, the educators, it must be said that the reacting influence upon pure science is least of all. Either they lead where the student of biologic science can not follow or they follow where the biologist leads.

At the opening meeting of this society a year ago an effort was made to present as an introductory to our work the broader bearings of paleontologic science in a form which might be read and understood of all men It was thought, and wisely, I believe, that in this way the society might declare at the outset a platform of helpfulness to the advance of human knowledge and thus to the progress of culture Those of us who were privileged to listen to this concourse of authoritative expression on the achievements and potentialities of the science must have felt that such a summation of its purport was needed I believe this society, now in its inception, would do well to keep before its eyes as the real objective of its existence, the fact that it must make itself immediately contributory to human culture and popular instruction if it is to achieve a worthy existence In our varied special interests we are somewhat forced to overlook these broader and perhaps more humane applications in the conviction that our work is its own justification, no matter how constrained its boundaries It is even so, but it was also a singular commentary I fear on the mental attitude of some of us toward what is really the supreme objective of our work that the council of this society decided not to publish this series of illuminating papers on the aspects of paleontology—and all the more a matter for congratulation that my successor to this office assured their publication in a magazine of wider and more popular circulation than the bulletin of the society.[3]

Rarely has there been given in any one place as satisfactory a summary of the philosophy and achievement of this sci-

[3] The papers delivered at the Conference on the Aspects of Paleontology at the first (Cambridge) meeting of the society have appeared in various numbers of *The Popular Science Monthly* for 1910.

ence Competent men in all cases and in many equipped to speak with supreme authority, presented the propositions of the science from the point of view of their special lines of interest, and though on every topic brought under consideration much more might have been effectively said, yet the sum of the matter was to set before the mind, in part at least in inimitable form, the scope of the science The very nature and diversity of our interests are both our weakness and our strength Our nature is trinitarian· whenever we cease to be held together by the centripety of a common broad unity, to keep our feet together on the platform of common concern, then we fly apart into our lesser orbits If I could venture therefore out of my experience with the larger world, to urge one consideration of paramount concern on my successors in this office, it would be that on these occasions of annual reunion sight never be lost of our major purpose and no risk ever be invited of swamping our unity in the sea of details Let us not blind ourselves to the beauty of the forest by seeing only the trees in it

II THE SIGNIFICANCE OF CERTAIN EARLY PARASITIC CONDITIONS

I propose now to turn your attention with reasonable brevity, and as a conclusion of this address, to a series of considerations which I am disposed to believe, when more fully illuminated by a patient and persistent accumulation of facts, may have a wider application to interests of immediate moment to society. In the acquisition of the evidences of the earliest phases of the parasitic or dependent condition of life I have been somewhat assiduous —enough at least to realize, as every one must in entering such a field, how much remains to be acquired and how many illustrations of it still lie in our great museums unrecognized or unstudied The appreciation of the parasitic conditions of to-day depends so wholly on the adaptations in the physiology and soft anatomy of organisms, that to seek such clues as these among the rocks may seem like entering a blind cavern without a torch Volumes have been written and volumes more would be necessary to portray the aspects of dependent life in living nature from the simplest organic subjection among the bacteria to the most complicated expression in human society, and with these before our eyes I believe it possible eventually to resolve from the record of the past the problems of the origination of such dependent conditions

Whatever attitude you and I may take as paleontologists toward the conceptions of Le Dantec and his followers, that the whole panorama of life is being renewed from its beginning every day in the scenes of the present world, these at least can not cover the transactions of organic dependence in which the time element is the most illuminating factor in its existence. What I have to offer at present is a very brief statement of a few suggestive facts and of certain justifiable inferences of broader scope which rank, I believe, in the category of continuous effects

In the effort to find the real significance of this vital relation I have purposely confined my observations, so far as the fossils are concerned, to those within the Paleozoic There have entered into the literature of fossil dependents straggling and usually quite incidental records of symbiosis in the eras later than the Paleozoic, but none of these eras which approach near to the present has added, so far as my knowledge extends, any essential clues to the origination of this condition. This is naturally so, for the advanced life of the Neozoic

times too closely approximates that of the present without carrying with it the solutions suggested by the soft bodies of to-day. Our statement of inferences in this problem must be very guarded because of our being bound down only to such records as the rocks have been able to retain But lest these evidences be underestimated, let me insist that nature has dealt kindly in the retention of the most intimate structures and here again, so far as skeletal remains go, we can safely fall back on her beneficence

Purely symbiotic mutualism is of very ancient date and we find frequent evidence of commensalism far back in Paleozoic faunas, of the same type of combinations as abound in the seas of to-day Thus there are few commoner examples of mutual associations in the present sea than those of the worms and corals, the worms and sponges, sessile cirripeds and corals, and I have elsewhere indicated a number of such occurrences in the Paleozoic There are the diffuse slightly curved tubes of the worm *Gitonia sipho* which traverse the fine-celled stratiform colonies of the coral Stromatopora in the Silurian and Devonian, the spiral worm Streptindytes of graceful form in the Silurian Stromatopora and one of heavier habit described by Calvin in the large-celled coral Acervularia of the middle Devonian The open apertures of tubes of *Gitonia corallophila* are often to be seen projecting from the cups and even the sides of the coral *Zaphrentis* and its allies These are simple associations in which the partners are and have always been equally and mutually dependent, both having begun life as independent free swimming beings Among these commensal worms and corals there is one association that invites particular notice in passing, for so far as I know the present fauna, its parallel is not recorded This is the compound coral *Pleurodictyum* and its worm *Hicetes*—an association long known to students of the Devonian, but not till recently, with the help of carefully prepared materials fully comprehended *Pleurodictyum* is a compound favosite growing in small, large-celled lens-shaped coralla of the size of a brussels sprout Its commonest species are *Pleurodictyum problematicum* of the European Coblentzian and *Pleurodictyum styloporum* of the Hamilton shales of America The sessile thecated base of the corallum in both these species seems to have attached itself to the rock or mud of the sea bottom in a way that involved the formation of no special cicatrix or scar of attachment My observations lead me to the conclusion that in the Coblentzian species such form of attachment occurred in about one half of the individuals and in perhaps somewhat less than one half in the Hamilton species The rest attached themselves at the beginning of the sessile stage to some organic object, some dead shell on the sea bottom In the Hamilton species in approximately one fifth of the cases, this dead shell was usually a gastropod of the genus *Pleurotomaria* or *Cyclonema;* in the remaining four fifths, the shell was always the same shell, a species of the gastropod *Loxonema* (*delphicola* = *hamiltonensis*) I have not recorded an instance of the coral being attached to any other than a gastropod, shell These are rather broad statements but are based on the examination of several hundred examples and are an approximate expression. These bases of attachment were of course dead shells which the free-swimming coral larvæ *selected.* I have italicized the word "selected" as, however else one may be disposed to interpret the phenomenon, the act bears a strange resemblance to conscious choice. The Coblentzian *Pleurodictyum* so similar in struc-

ture as almost to veil specific difference, has however chosen differently. I can not say that I have seen a wholly convincing number of German specimens, though probably I have had opportunity, by the help of collectors and the collections of many museums, of seeing as many as any one else, and I have further had the benefit of accounts given by various workers An approximate half of the German specimens, rather more than less, are unattached For the remainder I have seen none that is not attached to the brachiopod *Chonetes sarcinulatus*[8] However these very strange facts may be expressed in accurate percentages, the palpable evidence remains, that the free and independent larvæ of these closely allied species of the same genus of coral have in one part of the world unerringly taken a brachiopod shell for a *pou sto,* while in another perhaps actually coeval sea they have not chosen a brachiopod but always a gastropod, and usually one and the same species of gastropod, for their sedentary maturity

Neither of these species of coral embryos was deprived of a choice The sea bottom of the Coblentzian and of the Hamilton stages teemed with all varieties of invertebrate remains Gastropods and brachiopods flourished alike on both An act of choice could not pertain to the degenerate and fixed adult condition of growth, but it is a matter of supreme interest that such an apparent act, in whatever psychological category it may find its place, did manifest itself in the higher stage of normal inheritance, the free and independent condition of early life.

I presume that in all the phenomena of commensalism which the early faunas of the earth have exhibited, the concurrence of the worm and the coral is the commonest Yet I have not observed it in faunas earlier than the Silurian, with possible reservation for the Ordovician The Cambrian faunas contain the vital elements necessary for such cohabitation, but have not shown any indication that this habit of interdependence had been formed so early, even though the degenerate condition of attachment had been abundantly acquired then and doubtless long before[9] I shall not enter into needless detail regarding other mutual associations of these early days, citing briefly, for convenience of reference to those who are interested, the cases of the corals *Favosites* and *Amplexus* recorded from the Niagaran of Iowa, of a worm in the bodies of the glass sponges, *Hydnoceras* and *Prismodictya* of the upper Devonian, of the barnacle *Paleocreusia* in a colony of *Favosites,* from the lower middle Devonian Onondaga limestone

In late stages of the Ordovician there are certain crinoids of the genus *Glyptocrinus* and other long-armed inadunates which when found with arms drawn together hold within them a round-mouthed snail shell of the genus *Cyclonema.* I have examined a number of these associations, but have seen in none of this age any evidence of actual attachment of the shell to the proct or any other part of the crinoid Evidently here the association was a loose one, the snail feeding on the fecal waste of the crinoid, hanging around the back door like a dog at a garbage pail It was not long after the inception of this habit, however, that an actual fixation ensued, and there are well-known cases in the faunas of the Silurian of both crinoids and cystids cemented by a muscular attachment over the proct of the host, so firmly as to hold

[8] *Pleurodictyum* of like Devonic age and with its *Hicetes* occurs both on the Bosphorus and the Maecuru River, Brazil, but we know nothing yet of its habit of fixation.

[9] At this meeting of the society Dr C D Walcott exhibited specimens of a Cambrian worm commensal with medusa

its place during all the procedure of fossilization. We can not say how enduring this condition of deject dependence was in the life of the individual of the Silurian, but the Devonian faunas and more especially those of the early Carboniferous when the crinoidea attained their maximum profusion, at once furnish abundant and well-known facts indicating that this habit had at least become so fixed that it began with a very early juvenile stage and continued probably till released by death. The domes of many crinoids in these faunas have shown by successive elliptical scars, of which the proct is the focus, left by growing shells, that the snail remained permanently and solidly devoted to this habit for probably all the later stages of its life. This is distinctly a case of true parasitism, not merely of that degeneration resulting from dependence which is universal in nature, but of absolute and abject dependence on the vital functions of another. During the maximum of the crinoids as well as of these capulids or limpets in the early Carboniferous time the attachment seems to have been not occasional, but to have attained the character of an actual habitude to which all members of the Capulidæ were liable even though not all really practised it. This singular condition endured during millions of years from its inception in the Silurian to its climax, but from the time of its general prevalence in the early Carboniferous on through the closing stages of the Paleozoic and through the long following ages up to the present we seem to lack any shred of evidence of its continuation. In very fact it seems as if in the long panorama of life through the varying phases of this great time interval, for the first time in all our knowledge of the parasitic life in all circles of existence (except where this has been influenced by the higher motives which govern humanity), that here nature had demonstrated the power in herself to rebound from such tendencies to degeneration, to give her creatures a sharp turn about and start them again on the upward path. What a splendid significance of salvation it would be for the tremendous majority of nature's apparently doomed races if there should lie herein even a slender ray of hope for the recovery of tendencies toward the normal upward progress which so many organisms have lost by the supervention of degenerate habits. We may not be entirely sure that this ray of hope for a lost nature really exists, for even though we have no evidence of the parasitic dependence of the gastropods upon the Echinoderma in all the ages of the Mesozoic and the Cenozoic, we do know that in the present sea all parasitic gastropods are parasites on the Echinoderma, the class to which the crinoids belong.

Crinoids are few to-day, to my knowledge no one has recorded on them the presence of parasitic snails, but their close relatives, the star-fish and sea urchins, are still beset by gastropods, often so modified by their degeneracy that their nature is hardly recognizable, and this parasitism too is fixed and beyond repair. In these cases which have been particularly studied by the Sarasin brothers, the parasite is still of the limpet type of structure, whether the host be starfish or sea urchin. There is a palpable vast difference in degree between this particular form of parasitism to-day and the association of limpet and crinoid in the days of the Carboniferous seas, the later irremediable, the earlier still not beyond repair, well established but clearly not beyond the control of the dependent. The great gap of positive evidence in the profoundly studied Mesozoic and Tertiary faunas which certainly should have af-

forded such factors had they ever existed, leaves us a reasonable propriety to construe the cessation of this parasitism as actually accomplished in Carboniferous times, and the recurrence of like associations among allied animals of the present an essentially new adaptation of the two. For nature has made these adaptations easily and degeneracy to the parasitic condition is one of the facile procedures of life, moving on apace with ever-increasing momentum toward race destruction Much more natural, much more logical, much better justified by well-known procedure in these easy adaptations, is such a proposition, than that after millions of ages of suppression the ancient abject dependence of the limpet on the crinoid should have reappeared as a direct inheritance out of the remote past It is to this point I would direct the major purport of this paper, for aside from all other questions of ancient parasitic conditions there is none yet of so profound biologic significance as this question raised by the parasitism of the Paleozoic gastropods on the crinoids Did the snails get over it? Did they conquer this habit of dependence and return to normal independence? Granted that the parasitic condition is but an expression of adaptation, yet it unfailingly involves degeneration Did the gastropod rebound from its degenerate adaptation and return toward the normal living which has helped to perpetuate its stock abundantly to the present in more self-reliant expression? I believe that all the positive and all the negative evidence we can now adduce on this deeply important subject favors the presumption that the habit was abandoned or at least, to speak in terms of simple casuistry, was lost We may give the counter proposition all the weight to which it is entitled, and I believe we ask too much of both evidence and presumption to seek in it a recrudescence of a transmitted acquired habit in the present after the lapse of untold millions of years between its appearances

Living nature can of its very essence present us with no such proposition as this Here the time element is of paramount importance and we are confronted then here by the single example in all known nature below man of the possible recovery of a normal upright tendency in organic living after a period of degeneration, of a case of what appears to be, deducting due allowance for possible uncovered records among profoundly studied geological faunas, an actual rebound from an adaptation to evil living back to the normal uprightness of independent life by the intervention of natural forces only I might cite to you additional interesting cases of the parasitic habit in Paleozoic organisms, but none which can now amplify the special point I have had in mind in bringing these succinctly to your notice For doubtless if nature could and did turn even an invertebrate sinner from the error of its ways once, she can do it again, she doubtless has done it more than once and her influences directed toward the demolition of such degenerating adaptations could not be restricted solely to lowly forms of life The supreme merit of the striking illustration I have been able to bring to your attention lies in the panorama of its history, its inception, its progress, climax and probable extinction Even though it may now stand alone, the argument from it could not be much altered nor greatly strengthened by supplementary cases, however it might be clarified by the verification of the negative evidence in the ages between the Paleozoic and the present. But so far is the evidence good and the logic sound that I need not hesitate to intimate that the parallelism between organic

and social parasitism is not a similitude Organic degeneracy and degeneracy in human society are not, I take it, a mere equivalence in terms, but a result in effects through stages of adaptation entirely comprehensible Sin, then, the expression of degeneracy, we may reasonably hope to believe and perhaps eventually to demonstrate from the facts of our science, is an error whose cure may lie within our own inherent impulses and whose existence may be terminated with the stronger growth of our intellectual and moral perceptions entirely within the sphere of nature herself.

JOHN M CLARKE

THE DISTRIBUTION OF THE COLLEGE MEN

THE *Yale News* has made an analysis of "Who's Who in America" for 1910–11 and finds in the book the names of 8,529 college men The data for fourteen institutions are given as follows

	Law	Medicine	Education	Science	Engineering	Ministry	Writing	Mining Eng	Journalism	Finance and Business	Government Service	Retired	Total
Harvard	158	92	175	111	25	48	77	6	59	41	43	15	813

SCIENTIFIC NOTES AND NEWS

THE officers of the American Museum of Natural History, who were elected at the annual meeting of the board, held February 13, 1911, are as follows *President*, Henry Fairfield Osborn, *First Vice-president*, Cleveland H. Dodge, *Second Vice-president*, J. Pierpont Morgan, Jr, *Treasurer*, Charles Lanier, *Secretary*, Archer M Huntington; *Acting Director*, Charles H Townsend, *Assistant Treasurer*, United States Trust Company of New York; *Assistant Secretary*, George H Sherwood By unanimous vote of the trustees, Professor Bashford Dean, Columbia University, was reinstated in his post as curator of ichthyology and herpetology The trustees also promoted Dr. W D. Matthew from acting curator to curator of the department of vertebrate paleontology. Barnum Brown, assistant curator of fossil reptiles and Walter Granger, assistant curator of fossil mammals, become associate curators

FOR the meeting of the British Association for the Advancement of Science, which is to take place this year at Portsmouth on August 30 and following days, under the presidency of Professor Sir William Ramsay, K C B, F R S., the following presidents have been appointed to the various sections *Mathematical and Physical Science*, Professor H H Turner, D Sc, F R S, *Chemistry*, Professor J Walker, D Sc, F R S, *Geology*, A Harker, M A, F.R.S, *Zoology*, Professor D'Arcy W Thompson, C B, *Geography*, Col C F Close, R E, C.M G, *Economic Science and Statistics*, Hon. W Pember Reeves, *Engineering*, Professor J H Biles, LL D, *Anthropology*, Dr W H. R Rivers, F.R S, *Physiology*, Professor J. S Macdonald; *Botany*, Professor F. E. Weiss, D Sc, with W. Bateson, F R S, as *chairman of the Sub-section of Agriculture*; *Educational Science*, Rt Rev. J E C Welldon, D D.

A PORTRAIT of Sir William Crookes by Mr. E A. Walton, has been presented to the Royal Society

PROFESSOR D. OLIVER, F R S, formerly keeper of the herbarium and library of the Kew Gardens, known for his important contributions to botany, celebrated his eightieth birthday on February 5.

MEMBERSHIP in the Prussian House of Lords has been conferred on Dr Wilhelm Waldeyer, professor of anatomy in the University of Berlin.

THE gold medal of the Royal Astronomical Society has been presented to Dr. P. H.

Cowell, for his contributions to the lunar theory and gravitational astronomy.

THE Hopkins prize has been awarded by the Cambridge Philosophical Society to Professor J. H. Poynting, F.R.S., of the University of Birmingham, for his researches on the transmission of energy in the electric field and on the pressure exerted by radiation.

THE *Journal* of the American Medical Association notes that in addition to the Nicholas Senn high school, the site for which has been secured, Chicago schools are named after the following physicians Daniel Brainard, William H Byford, Nathan Smith Davis and Charles Warrington Earle

MR. F W DYSON, F R S, astronomer royal, and Surgeon-General Sir Alfred Keogh, K.C.B., rector of the Imperial College of Science and Technology, have been elected members of the Athenæum Club for their scientific work.

M G BIGOURDAN has been appointed president of the Bureau des longitudes, Paris M B Baillaud is the vice-president and M H Andoyer, the secretary.

DR HENRY SKINNER has resigned the editorship of *Entomological News*, taking effect with the number for December, 1910 He had been editor continuously since March, 1890, since which time the journal increased in size from 168 pages and no plates to 484 pages and 14 plates per annum. The journal is in charge of the joint publication committee of the Entomological Section of the Academy of Natural Sciences of Philadelphia and of the American Entomological Society. This committee accepted Dr Skinner's resignation with regret and elected Dr Philip P. Calvert (associate editor since January, 1893) editor, Ezra T. Cresson, Jr associate editor, and Dr. Skinner editor emeritus

AT a meeting of the American Philosophical Society on March 3, Professor F M Jaeger, of the University of Groningen, will read a paper "On Fluid Crystals and Bi-refringent Liquids."

PROFESSOR L. H. BAILEY, dean of the Agricultural College of the State of New York, appeared as the ninth lecturer upon the J C Campbell Foundation of the Sigma Xi Society of the Ohio State University on the evening of Wednesday, February 8 He spoke upon the subject "The Country Life Movement."

DR. M P. RAVENEL, head of the department of bacteriology, represented the University of Wisconsin at the meeting of the American Association of School Hygiene, where he read a paper on "The Function of University Faculty Committees on Hygiene"

DR. M B. THOMAS, of Wabash College, recently lectured to the Illinois State Horticultural Society on "The Nature of Parasitic Fungi and their Relation to Their Hosts"

THIRTY-SEVEN professors from the University of Wisconsin appear on the program of the annual meeting of the Wisconsin Academy of Sciences, Arts and Letters, the Wisconsin Archeological Society, the Wisconsin Mycological Society and the Wisconsin Natural History Society, which opened in Madison, February 17 The opening address of the first day was on "The Relation between Area and Temperature of Lakes," by Dean Edward A Birge, of the college of letters and science Fifteen addresses were made by members of the university departments of geology, botany and zoology

DR EDWARD HITCHCOCK, for fifty years professor of hygiene and physical education at Amherst College, died on February 15, aged eighty-two years

PROFESSOR FRANK J PHILLIPS, head of the department of forestry in the University of Nebraska since 1907, died on February 13, at his home in Lincoln, Nebraska. He was a graduate of the Michigan Agricultural College and the University of Michigan, and had spent several years in the United States Forest Service before his connection with the University of Nebraska. He was the author of a number of important scientific papers and was one of the most brilliant teachers that the university has known

DR. M. WILHELM MEYER, known for his contributions to astronomy, and his efforts to

popularize this science, has died at Meran at the age of fifty-eight years

The death is also announced of Dr Sigmund Grundfienger, formerly professor of mathematics at Darmstadt

Herr Leopold Koppel, a Berlin banker, has given $175,000 for the erection of a research institute for physical chemistry in Berlin and will make a further gift of $87,500 extended over the next ten years for maintenance

The senate has passed the Weeks bill providing for the establishment of a forest reserve in the Appalachian Mountains by a vote of 57 to 9 The bill is applicable from Maine to the Gulf of Mexico, on the eastern seaboard It was passed by the house at the last session The bill gives the consent of Congress to the states to enter into an agreement among themselves for the purpose of conserving the forests and water supply of each, and appropriates $200,000 to enable the secretary of agriculture to cooperate with such states in giving fire protection In addition, the bill appropriates $1,000,000 for one year, and not more than $2,000,000 for each year thereafter, until 1915, for surveys, examinations and acquirement of lands located at the headwaters of streams which are being or may be developed for navigable purposes A commission composed of the secretaries of war, interior and agriculture and of two members each of the house and senate is created to acquire these lands subsequent to an examination by the Geological Survey

It is reported in *Nature* that at a special general meeting of the Geological Society of London on January 25, the following resolutions were passed (1) That the space now occupied by the museum be made available for the extension of the library (2) That it is desirable that the society's collections of fossils, minerals and rocks, with certain exceptions to be subsequently specified, be offered to one or more of the national museums, provided that guarantees be obtained that the specimens will be properly registered and rendered available for scientific purposes. (3) That it is not desirable that the society should accept money for any part of the collections, or in consideration of them. (4) That the council be empowered to approach such institution, or institutions, with the view of carrying the above resolutions into effect, and that the council shall call another special general meeting to express approval or otherwise of the arrangement proposed

The late Dr Huchard has bequeathed to the Académie de médecine a sum of $20,000 to found an annual prize to aid young students, who like his son, Marcel Huchard, in whose memory the prize is founded, are victims to professional devotion and to enable them to continue their studies

A catechism on bovine tuberculosis is the title of a circular of information issued by Dean H L Russell, of the college of agriculture of the University of Wisconsin, and Professor E. G Hastings, of the university experiment station. This bulletin presents over sixty questions gleaned from inquiries received at the college with brief answers based on the best scientific knowledge of bovine tuberculosis Complete instructions for determining the presence of the disease through the administering of the tuberculin test are given, together with hints on how to control the disease in a large herd

The operation of amblygonite mines in South Dakota during the last two years has reduced the price of lithium carbonate from $2 50 to 50 cents a pound, and large quantities have been sold at still lower prices The carbonate is the lithium product most used and is employed in making storage batteries and fireworks and for medicinal purposes. Lithium, the metal, has no practical use Lithium bromide is used to some extent in photography and in medicine. In an advance chapter of the United States Geological Survey's volume entitled "Mineral Resources of the United States, Calendar Year 1909," prepared by Frank L Hess, the occurrence and extraction of lithium ores are discussed In 1909 several carloads of amblygonite were taken from mines at Keystone, S. D., and a few carloads of spodumene were shipped from the same locality by another company Practically all

the lithium compounds prepared in the United States in 1909 were extracted from these ores.

THE department of public health at the American Museum of Natural History has equipped a laboratory to serve as a central bureau for the preservation and distribution of bacterial cultures of both pathogenic and non-pathogenic organisms, and particularly of types of new forms and varieties It is hoped that the laboratories of medical schools, colleges, boards of health, agricultural experiment stations, etc, and those engaged in biochemical work of all sorts, will furnish the museum with cultures at present in their possession, and the laboratory is now ready to receive and care for such cultures Only organisms which have been identified and which have a definite history are desired as a rule, but in the case of rare species, like the organisms of certain tropical diseases, this rule may be departed from The laboratory can not undertake to maintain more than fifteen different strains of any particular form Types of new species and varieties are particularly desired at the present time and as they may be isolated in the future The laboratory plans also to keep on file descriptions of bacterial species in print or arranged in the form of the standard card and will be grateful for copies of any such descriptions Descriptions filed in the department will be carefully preserved and living cultures will be kept in good condition, so far as possible, and will be supplied at all times without charge to corresponding laboratories and furnished so far as possible and with a reasonable charge to schools and other institutions which may desire cultures. The laboratory, of course, can not undertake to keep on the difficultly-cultivable bacteria, such as can be maintained only for a few weeks after isolation from the body; neither can it at present supply virulent cultures which rapidly lose their virulence under laboratory conditions. It should, however, be able to furnish cultures of organisms of all the ordinary types, which can be maintained under cultivation Pathogenic forms will be sent only to properly qualified persons.

UNIVERSITY AND EDUCATIONAL NEWS

IT is announced that Professor Hans Meyer has presented 150,000 Marks to the University of Leipzig for the laboratory of experimental psychology established by Professor Wilhelm Wundt.

THE New Hampshire College of Agriculture and Mechanics Arts will continue under that name, the house of representatives of the state not having approved a change to the University of New Hampshire

A SCHOOL for forest rangers to consist of a two-year course, the winters of which will be spent at the university, and the summers in practical work on the state forest reserves, or in lumbering operations in the field, is proposed to be started at the University of Wisconsin Outside the Pennsylvania ranger school and those established by the federal forest service in connection with some of the far western institutions, no attempt has been made to meet the demand for expert foresters It is thought that much of the work of the course in forestry could be given in the present departments of the colleges of engineering and agriculture The state department of forestry would probably need all the trained men that the school of forestry could turn out for a number of years

THE newspapers report that following the student disorders in Russia one hundred and twelve professors have resigned or been dismissed. It is further said that the ministry of education in order to attract professors in other countries plans to establish temporary Russian schools of law in Berlin and Paris, a school of natural sciences at Heidelberg and one of medicine at Paris

IT is announced that Dr George E MacLean has resigned the presidency of the State University of Iowa, and that Dr. Edmund A Engler has resigned the presidency of the Worcester Polytechnic Institute

MR. FRANK HOWSON, of the University of Durham, has been appointed lecturer in physiology at Sydney, New South Wales.

DISCUSSION AND CORRESPONDENCE

BOTANICAL EVIDENCE OF COASTAL SUBSIDENCE

IN a recent number of SCIENCE[1] Mr. H. H. Bartlett, writing under the above title, criticizes an earlier paper of my own concerning "The Supposed Recent Subsidence of the Massachusetts and New Jersey Coasts,"[2] on the ground that it represents hasty conclusions based on the examination of one locality where conditions are far from typical. Mr. Bartlett is of the opinion that the hypothesis there advanced to account for the appearances of recent subsidence along the coasts in question has "as a matter of fact . . . no bearing whatever on most of the evidence which has been offered."

Inasmuch as the brevity of my paper may be responsible for Mr. Bartlett's failure fully to understand it, perhaps a few words as to the development of the hypothesis presented in that paper may serve to make the hypothesis itself clearer. The writer's active interest in the problem of subsidence began a number of years ago when he was retained by counsel for the commonwealth of Massachusetts, in a case involving title to lands now below high tide level, to determine if possible the nature and extent of the recent subsidence along the Massachusetts coast. He entered upon this investigation with the belief that recent coastal subsidence in this district was a fact, well established by the studies of various students of shoreline phenomena; and his efforts were mainly directed toward ascertaining whether the subsidence was continuous in time and regular in rate, or whether it was intermittent and at varying rates. In connection with this investigation examination was made of numerous publications on recent changes of level in the United States and Canada, and many foreign reports on the same topic; and so fair familiarity with the literature of the subject was gained.

Even before undertaking the above investigation, certain geologically recent changes in the form of the shorelines about Boston had attracted the writer's attention; and in the succeeding years more or less consideration has been given to this subject. Several of his students have made special studies of selected areas along the coast, in each case giving attention to the problem of coastal subsidence. Their observations and his own, supplemented by studies of maps of certain areas not visited, led the writer to conclude that the coast had remained essentially stable for a long period of years, and that if any considerable subsidence had taken place, it must have occurred long ago.

The botanical evidence of recent subsidence was still a puzzle. Manifestly, the uppermost layers of the *Spartina* turf, and the stumps of cedars and other trees exposed in the marshes, could not be due to a remote subsidence, even if the lower layers of turf and the more deeply buried stumps had been depressed long ago. Careful attention has been given to this phase of the problem, and in this connection let me express my great indebtedness to Dr. Charles A. Davis, who gave me the opportunity to accompany him on several of his field excursions, and who took the time to visit with me two or three localities where I had studied the physiographic features of the shoreline. On these excursions I became fairly familiar with the botanical evidence of subsidence, and with the interesting methods of investigation which Dr. Davis has developed for the study of salt marsh deposits. By means of the ingenious peat sampler devised by Dr. Davis, the writer has endeavored to increase his knowledge of the structure of several of our marshes; and one of his students has made a detailed series of sections across the marshes at the mouth of the Neponset River, which will be referred to in a future publication.

As a result of these studies, it seemed to the writer that while the lower portions of the marsh deposits might indicate subsidence in times long past, the upper portions (the portions which furnish supposed evidence of *recent* subsidence) might be explained in either one of two ways: they might represent a resumption of the downward movement of the coastal region in recent times, after a long

[1] SCIENCE, N. S., XXXIII., 1911, 29–31.

[2] SCIENCE, N. S., XXXII., 1910, 721–723.

halt; or they might be explained as the result of local fluctuations of marsh level or of tide level, independent of a downward movement of the coastal region. The long halt in the supposed downward movement seemed to be demanded by the physiographic evidence.

Observations in the Scituate-Marshfield region revealed a cause of fluctuations in high tide level which appeared competent to explain most, if not all, of the evidences of recent subsidence. After a consideration of the tidal conditions along the Atlantic coast, and a study of the nature of the high tide surface about the coasts of England, as reported by Wheeler and others, the conclusion was reached that the conditions in the Scituate region had been repeated in a greater or less degree all along our coasts in recent geological times, as a necessary consequence of the nature of the high tide surface and the changes effected by wave action on all shores, particularly those composed of poorly consolidated materials. The cause seemed competent to explain a deposit of peat varying in thickness from a few inches to a possible maximum of 15 feet or more, according to the former range of the tides. As all of the supposed evidence of *recent* subsidence on the Massachusetts and New Jersey coasts are, so far as known to the writer, capable of explanation on the basis of a fluctuating high tide surface, and as the conditions on those coasts make such fluctuations in the past a seeming necessity, and as the physiographic evidence, on the Massachusetts coast at least, points to a long period of coastal stability in recent times, the conclusion seems reasonable that, while subsidence in the past may have occurred, the evidence of recent subsidence in these two areas is not decisive. Further study convinces me of the correctness of that conclusion. But whether it is correct or not, it was not reached with undue haste, nor was the botanical evidence of subsidence "lightly disregarded."

When a problem that has been discussed for many years, on the supposition that it involves but x factors, is found really to involve $x+1$ factors, all of the earlier conclusions should be carefully reconsidered; not that they are necessarily wrong, but because it can not be known that they are right until the additional factor is fully considered along with the others. The problem of recent subsidence of the Atlantic coast has long been discussed, but the importance of a high tide surface which fluctuates with changes in the form of the shoreline, as a possible explanation of this apparent subsidence, does not appear to have been considered in the published discussions of the problem. It is an element of possible value in all cases of tidal shores which are irregular in outline or which are bordered by barrier beaches. Hence all conclusions which have been reached in regard to recent subsidence in such cases ought to be revised in order to take this element into account. What the result of revision in each case will be can not be foretold, and for this very reason the revision seems the more necessary. The writer is attempting such a revision for several localities, without prejudice in favor of any particular conclusion, and in most of the cases without any idea as to what the final result will be.

My statement as to the inconclusiveness of the evidence of recent subsidence on the Massachusetts and New Jersey coasts, was made after a careful reading of Mr. Bartlett's very interesting paper on the sub-marine *Chamæcyparis* bog at Woods Hole, Mass. Although this paper presented a most ingenious and interesting argument in favor of recent subsidence, the validity of the argument depended upon certain assumptions which seem to me untenable. It was not the object of my brief paper to discuss the voluminous evidence in favor of recent subsidence, but rather to make a short preliminary announcement of an hypothesis which appeared to be of considerable importance, for this reason I did not deal specifically with Mr. Bartlett's observations. Full attention will be given to all accessible evidence in favor of recent subsidence in a future publication.

A careful reading of Mr. Bartlett's criticism of my paper leads me to think that he has failed to discriminate sufficiently between low-lying peat deposits which may be of consid-

erable antiquity, and the uppermost deposits unquestionably of modern date which alone can be invoked as evidence of recent subsidence It would appear, also, that he has not clearly understood my paper, for it is otherwise difficult to account for such statements as "the hypothesis of a fluctuating high-tide level has no possible application" to the botanical evidence of present subsidence as presented by Dr Davis, or that the hypothesis "has no bearing whatever on most of the evidence which has been offered" Surely if the height of ordinary high tides gradually rises one or more feet as the result of changes in the form of the shoreline without change in the level of the land, this increase in tidal height will produce all of the phenomena which would be produced by actual subsidence of the land, "now going on" The task which confronts the student of shoreline changes involves a discrimination between different causes producing like results, and the best method of making such a discrimination is, in the opinion of the writer, to deduce the character and magnitude of the results which each hypothetical cause is theoretically capable of producing under the varying conditions which exist along an irregular coast, and then to compare the deductions with the actual phenomena as observed in the field So far as I have carried such an analysis for the Massachusetts coast, the evidences of supposed recent subsidence are all capable of interpretation on the basis of a fluctuating high tide surface, whereas physiographic features of much importance seem incompatible with the theory of continued recent subsidence

MIASTOR AND EMBRYOLOGY

Reproduction by insect larvæ, a form of parthenogenesis known as pedogenesis, is extremely interesting. The writer was fortunate last fall in finding, in the partially decayed chestnut bark of a rail fence, numerous *Miastor* larvæ, forms not previously recognized in this country, though several species and representatives of allied genera have been studied by a few Europeans. *Miastor* larvæ and their allies should be of great service to teachers of zoology and biology, since they admit of the study at first hand of this interesting phenomenon It is possible, with a no more elaborate outfit than an ordinary student's microscope equipped with a three-fourths objective, a microscopic slide and a few cover-glasses, to observe the vital activities of the young larva, to see the muscular, respiratory, digestive and nervous systems, to identify the ovaries and to watch the gradual development of the semi-transparent embryos within the body of the living mother larva Furthermore, these forms are well adapted to more exact histological methods, being soft and therefore excellent subjects for serial sections and stains, particularly as it is comparatively easy to secure from one colony a series of individuals representing different stages of development

Aside from the interest attached to their morphology and biology, there are other considerations which should appeal strongly to the teacher of zoology These larvæ are widely distributed and, with an understanding of their habits, there should be little difficulty in finding them They are small, and a piece of wood six inches long, three inches wide and half an inch thick, may contain or produce enough material for a fair-sized section or class The larvæ are prolific and, under favorable conditions, would probably multiply at any season of the year This is certainly true of the fall, the early winter and the spring. They can be kept alive for at least a month in microscopic cells, and with care a larval generation will develop in such restricted quarters. We have kept larvæ healthy and multiplying for nearly three months with nothing more elaborate than a moist piece of decaying wood clamped lightly to an ordinary microscopic slide and kept in a moist, dark box. Many of the larvæ were content with conditions on the surface of the wood, next the glass, and were therefore easily observed These remarkable larvæ are very hardy; prolonged dryness simply results in a suspension of activities, while they are quite resistant to an abundance of moisture. Embryos will continue their development in mother larvæ even

though the latter be kept for weeks in a sealed cell filled with water. It is even possible to make very satisfactory photomicrographs of living embryos within the mother larvæ, while there is not the slightest difficulty in observing the movements of those nearly fully developed before their escape from the mother integument. With our present knowledge we see no reason why artificial colonies of this insect might not be established in the vicinity of a zoological laboratory and maintained with very little or no attention from year to year, if not for a decade or more. A detailed account of this species, with a number of illustrations will appear shortly in the writer's report for last year.

E. P. FELT

TREMATODES OF THE DRY TORTUGAS

MY friend Albert Hassall has called my attention to two of the new generic names which I employed in a recent paper on the Trematodes of the Dry Tortugas.[1]

The generic names *Didymorchis* and *Mesorchis* are preempted, thus making it necessary to invent other names to take their place. I therefore propose for *Didymorchis* the name *Pycnadena* (πυκνὸς packed close, and ἀδὴν a gland), and for *Mesorchis* the name *Antorchis* (ἀντίος opposite, and ὄρχις).

These two specific names hence become *Pycnadena* (n. g.) *lata* (Lt.) and *Antorchis* (n. g.) *urna* (Lt.)

At the suggestion of Mr. Hassall I take advantage of this opportunity to state that *Deradena ovalis*, *Hamacreadium mutabile* and *Genolopa ampullacea* are the type species of their respective genera.

QUOTATIONS

COMMERCIALISM IN EDUCATION

THAT the methods of higher education are in a state of transition in this country appears evident from the pedagogic innovations made and the many more proposed during the past several years. On the one hand, colleges of higher standing are elevating their curricula to a real professional plane, apparently having at length found it too difficult, to say the least, to instruct in the same course men for such different callings as dynamo tender and consulting engineer. On the other hand, some schools are frankly revealing that their aim is to serve, not the interests of the student, but solely those of the employer of technical graduates, even though education directed primarily to this narrow purpose may unfit the subject for obtaining the most out of life spiritually, through lowering his ideals and curbing his ambitions, and financially, through making him a mere serf to an industry. A concrete illustration of the haphazard condition of thought concerning technical education is afforded by a recent report of the Carnegie Foundation for the Advancement of Teaching on "Academic and Industrial Efficiency," prepared by a well-known and doubtless capable "efficiency engineer," whose business is concerned with the economical administration of manufacturing establishments.

While we have no quarrel with the efficiency engineer as such, nor with his efforts in the course of business to report upon any problem which his clients may desire investigated, we can not refrain from expressing astonishment at the frame of mind of one who would direct the application to instruction in science of the canons appropriate for running a purely money-making business. The possibility of such a distortion of view is the most serious criticism that could possibly be launched against American educational methods. As well put a skilful and successful sausage maker at the task of criticizing the manufacture of astronomical telescopes. An institution for training young men in science, whether pure or applied, is not a money-getting concern. Its product is not sausages, but the advancement of human intelligence, which may or may not be applied to gainful objects. Even in the narrowest technical sense it does

not turn out a standardized product of salable packages of information, but an infinitely variable and intangible thing the importance of which to the world can not be measured by the demand for it reckoned in dollars and cents The world ultimately owes far more to the institution which produces men who guide the world's destinies in any department of activity than it does to the graduate factory that adds yet more to the rank and file of the mediocre This at least is the situation regarding the very class of institutions the investigation of which was undertaken in the report before us Its whole tenor was to lay emphasis upon the destruction of the academic freedom and initiative that is necessary to the advancement of human intelligence and to promote that kind of organization which, under the disguise of uniformity and system, effectively suppresses progress It is an application to educational institutions of the methods too common in American manufacture, which insure a large output of the tolerable rather than a small output of the desirable—*The Electrical World and Engineer*

SCIENTIFIC BOOKS

Theorie physico-chimique de la vie et générations spontanées Par STÉPHAN LEDUC, professeur à l'école de medicine de Nantes Paris, A Poinat 1910

Life as a physico-chemical process, and the analogy between living and lifeless, would possibly have been a better heading for this little book of Professor Leduc, for it does not consider spontaneous generation in the fashion which the reader is apt to expect from its title On the other hand, it may well be that the post-Pasteurean biologist is over-sensitive as to the words "spontaneous generation," and he is apt to give them in latter days a cabalistic meaning. he inclines to dismiss the rare papers which deal with the theme as anachronisms—and he is careful not to recommend them to publishers Even the French Academy has become so modern that it will not admit to its shelves any treatise which deals with this "exploded theory"!

Nevertheless, a whisper comes occasionally out of the wilderness and reminds us that this is the problem of all biological problems and that it is still neglected Perhaps our conscience is touched by the feeling that if we are consistent evolutionists we must have some manner of faith that the living came from the lifeless, and that, in the pursuit of biological happiness, we have been drifting in past years towards vitalism in some type or another We recall too, that in the last decade, steps have been taken in the analysis of biochemical phenomena, in matters of enzymes, catalyzers, ions, tonicity and similar physical facts which have all an intimate bearing upon organisms and are paving the way for a new biological era After all, many of us are convinced mechanists, and there should therefore be no reason why a book like Leduc's, title and all, should not be welcomed It is certainly the first work to bring up to date the documents upon which a synthetic biology—as distinguished from descriptive and analytical—may be founded

Let us see how his theme is handled: There is as yet no satisfactory definition of life: in spite of the efforts of many biologists, we know it by its presence or absence, by phenomena of nutrition, sensibility, growth, organization, reproduction, processes all of which are known in some degree in the inorganic Moreover, as Leduc declares, life is in itself different in quality in its different manifestations in various organisms, thus he leads us to infer that the life of man differs more widely from the life of a protozoan than the life of the protozoan from the "life" of liquid crystals, for example Life is to be studied as the transformer of matter and energy, it is a specialized phase of matter, the organic as opposed to the inorganic, and like a current it changes ephemerally. Its expression can best be studied in nutrition and in morphogenesis And these are the lines of study which the author has developed. Nutrition is in essence chemico-physical, especially concerned with the phenomena of contacts between fluids of different characters, whether electrolytic, osmotic, colloidal, crystalloidal In this connection he considers the laws of solutions,

matters of molecular concentration, osmotic tension, cryoscopy, periodicity, Ostwald's surface energy, relations to thermodynamics, diffusion, fields of force, all considered as elementary factors which enter into the synthesis of organic phenomena In the matter of diffusion Leduc's experiments show curiously close parallels with organic processes, producing geometrical forms, circulation of "cytoplasm," "life" which survives freezing or drying, pseudosegmentation of a "germ," and phantoms of karyokinetic figures Especially striking are osmotic growths, which are unquestionably the most complete parallels between the lifeless and the organic which have been devised Following Leduc's formulæ one may cause "organisms" to grow which are curiously like algæ or fungi Leduc points out that they will grow roots, stems and "fruit," the last sometimes appearing quite different in color The growths have their periods of "youth, maturity, senility and death," they exhibit periods of activity and rest, they show cell-like divisions, definite form relations, and a circulation of their fluid contents, they will repair wounds, and show responses to external and internal stimuli Peculiarly sensitive are these colloidal osmotic productions to changes in milieu thus those "growing" around the sides of a jar will occasionally behave differently from those in the middle. Each salt, it appears, has its specific morphogenic properties With some salts the "productions" are first attached they then become amœboid and motile, sometimes forming spicules at the surface The degree of concentration of the solution, also, determines sensitively the branching or the heaviness of the growth, the outcome of reactions which Leduc compares, by numerous chemical formulæ, to metabolism.

Altogether Leduc's book is interesting and it deserves to be carefully read We need not admit that it is biology; but we must admit that the inorganic conditions which here are given detailed consideration have occurred and are occurring constantly in organisms. And we shall be apt to admit that the synthetic method promises results which will prove of great value Leduc would be the first to agree that living substance may not be synthetized for ages, if at all But each advance brings the goal nearer, in the solution of single problems, and even of their separate components Leduc points out the immediate task of synthetists, and an essential one, is not the artificial production of albumenoids, but of a chlorophyllian substance which will decompose carbon-dioxide dissolved in water and be capable of assimilating carbon In this direction one recalls the interesting notes of Matthews and of McPherson in recent numbers of SCIENCE

BASHFORD DEAN

Praktikum der Bakteriologie und Protozoologie Von KISSKALT und HARTMANN Zweite, erweiterte Auflage Zweiter Teil Protozoologie Von Dr M HARTMANN. Pp vi + 106 Mit 76 teils mehrfarbigen Abbildungen im Text Jena, Gustav Fischer 1910 M 4

The task of securing adequate laboratory material for instruction in protozoology has been considerably simplified by the "Praktikum" of Kisskalt and Hartmann The author of the second part, Dr Hartmann, is the director of the laboratory of protozoology in the Royal Institute for Infectious Diseases at Berlin, a pupil of Professor R. Hertwig and the successor of Schaudinn as editor of the *Archiv fur Protistenkunde* The work is therefore authoritative and reflects the current practise in one of the greatest centers of research. The hand-book is written primarily for the medical student and includes only parasitic forms and especially those of medical interest It is not a book therefore primarily for the biological laboratory though the range of forms it discusses is sufficiently wide to make the work indispensable to every student of the protozoa, and of greatest value in all laboratories in which the protozoa are studied

The second edition has been considerably enlarged by the addition of a section on the technique of investigation in protozoology and by a chapter on the Myxosporidia and the Sarcosporidia. A number of new parasitic

types, principally from culture animals, have been added, including *Amœba lacertæ, A diploidea, Entamœba muris, E. tetragena, Trichomonas muris, Lamblia* (and *Octomitus*) *muris, Leucocytozoon siemanni, Proteosoma præcox* and *Balantidium coli*

The plan of treatment is comprehensive, including general introductions to each group, and detailed accounts of the morphology and life history of each of the forms discussed together with directions for securing, controlling, cultivating and preparing the material for study Illustrations often in color, illustrate the various stages and assist materially in the interpretation of laboratory material Brief bibliographies of a few pertinent papers are appended

It is to be regretted that the student of *Babesia canis* is left uninformed of Nuttall's work, that Fantham's work as well as Schellack's on spirochætes is not cited and that the sexual phase of the cycle of *Trypanosoma lewisi* is described as reported by Prowazek in *Hæmatopinus* without any hint as to the reserve with which his conclusions on this point have been generally received This lack of caution is all the more regrettable in the light of Minchin's experiments with fleas as carriers and Doflein's recently published results of his experimental cultures and his conclusions as to the necessity of caution in interpreting stout and slender forms as sexual gametes and their conjunction as conjugation

No chapter on technique of parasite flagellates is complete either historically or technically without calling the student's attention to the culture methods of Novy and MacNeal. Such omissions as these are hardly to be condoned by the fact that the author is writing primarily for the German student.

The figures are often original and are uniformly excellent. The condensed but comprehensive and lucid account of the significant features of the structure and life history of the important pathogenic and parasitic types available for laboratory use will be of greatest assistance to the student in this difficult field.

CHARLES A. KOFOID

BERKELEY, CAL.

TRIPHENYLMETHYL

SINCE modern methods of formulation were established, organic chemists have been able to represent the many thousands of compounds, whose constitution has been elucidated, by formulas in which the carbon atoms are always tetravalent The single exception was carbon monoxide, CO, in which the carbon is necessarily represented as being bivalent

In view of these facts it was natural that Gomberg's discovery of "triphenylmethyl," $(C_6H_5)_3\overset{*}{C}$, should arouse widespread interest, because, if it be correctly formulated, the carbon atom marked * is trivalent During the ten years which have elapsed since Gomberg's discovery was first announced, a very large amount of work has been carried out in order to elucidate the true nature of triphenylmethyl The most important contributions, which are summarized below, have been made by Gomberg himself, by A E Tschitschibabin, A von Baeyer and more recently by W. Schlenk[1] and his co-workers in Baeyer's laboratory

"Triphenylmethyl" is prepared by the action of certain metals, such as zinc, on triphenylchloromethane, $(C_6H_5)_3CCl$, the metal simply removes the chlorine atom "Triphenylmethyl" exists in two forms, a white, solid modification, which is relatively stable, and a soluble yellow form exhibiting very great chemical activity This colored variety has a molecular weight corresponding to the simpler formula, $(C_6H_5)_3C$

As regards the colorless material, the facts pointed to its being hexaphenylethane, $(C_6H_5)_3C\cdot C(C_6H_5)_3$, but many chemists hesitated to accept this view, chiefly, perhaps, for the following reasons. The substitution of phenyl groups for hydrogen in hydrocarbons results, in general, in an increase in the stability of the product, consequently, in passing from ethane, $CH_3\cdot CH_3$, to hexaphenylethane, $(C_6H_5)_3C\cdot C(C_6H_5)_3$, we should expect to obtain an inert substance, but we find that the "hexaphenylethane," mentioned above, is so unstable that its mere solution, at the ordi-

[1] *Ber d. chem. Ges.*, 43, 1753, 3541, 1910.

nary temperature, causes its decomposition into "triphenylmethyl," $(C_6H_5)_3C$

An investigation of the ethanes containing a smaller number of phenyl groups, from one up to five, would obviously be calculated to throw light on these points This work has been carried out and it has been found that a very stable compound, which was formerly regarded as being hexaphenylethane, actually possesses a different constitution It has also been shown that, in certain respects, there is a decrease in stability and an increase in chemical reactivity as the number of phenyl groups in the ethane molecule becomes greater Thus, for example, pentaphenylethane, $(C_6H_5)_3C \cdot CH(C_6H_5)_2$ is decidedly less stable than tetraphenylethane, $(C_6H_5)_2CH \cdot CH(C_6H_5)_2$

The final link in the chain of proof has been furnished by Schlenk, who has just shown that if the pentaphenylethane be heated with a neutral solvent of high boiling point, it is decomposed into triphenylmethyl and tetraphenylethane, in the manner indicated by the dotted line in the formula,

$$(C_6H_5)_3C \vdots CH(C_6H_5)_2,$$

the tetraphenylethane results, of course, from the combination of two of the groups, $CH(C_6H_5)_2$ It follows, therefore, that there is no difference, in principle, between the behavior of pentaphenylethane and hexaphenylethane towards solvents, when in solution, both give triphenylmethyl, the latter at the ordinary temperature, the former only when it is heated

In view of these results there is no ground for doubting that the colorless solid obtained by Gomberg is really hexaphenylethane, $(C_6H_5)_3C \cdot C(C_6H_5)_3$, and that its passage into solution, at the ordinary temperature, suffices to resolve it into two molecules of colored triphenylmethyl, $(C_6H_5)_3C$

MCMASTER UNIVERSITY,
TORONTO, CANADA

SPECIAL ARTICLES

SUGGESTIONS AS TO THE CULTURE OF BUTTERFLIES

BUTTERFLIES, with their clear-cut color patterns and brilliant hues, their remarkable polymorphism seen in the occurrence within a single species of two or more seasonal forms, or of melanic, albinic or other varieties often limited to individuals of one sex, furnish a most inviting field for the student of evolution and heredity The fact that in America, at least, no precise and long-continued work on heredity in diurnal lepidoptera has been undertaken hitherto is probably due in part to the belief that the mating of butterflies, occurring usually in the air, would be difficult to bring about in small cages; though the mating of moths under such conditions is generally known to be an easy matter It is my purpose in this article to correct this false impression in regard to the mating of butterflies, and to make other suggestions as to methods of caring for this dainty live stock, of marking individuals to indicate their pedigree, and of preserving them in a more compact, permanent, convenient fashion than the usual impalement on long pins in bulky drawers or boxes

One who undertakes the study of the heredity of butterflies may of course begin either with live wild females, presumably already impregnated, or with eggs already laid, with larvæ, or with chrysalids. For transportation over long distances chrysalids, or eggs upon the food plant, are usually to be prefered Living plants with roots intact and leaves covered with eggs may be shipped in tin boxes by mail. But often only the imago can be obtained In this case, and always, if the distance is not too great, sending live butterflies by mail in strong, cylindrical tin boxes lined with moist blotting paper that is held firmly in position is to be recommended. I have found that *Colias philodice*, shipped 150 miles in this way, and shut up closely for eighteen hours, stands the journey well, and lays abundantly, if well fed with sweetened water upon arrival.

For purposes of identification it is of course necessary for the student of heredity to label each living adult butterfly. This is readily done by writing the sign of the family and individual with pen and ink upon the under

surface of the hind wings. Since aqueous ink will not flow readily enough, the pigment used should be dissolved in 50 per cent alcohol, and applied with light strokes of a stub pen Anilin dyes are convenient, as they are readily soluble and can be obtained in almost any color, but for general use any carbon ink that is not precipitated by mixing with 50 per cent. alcohol is preferable, because more permanent. The live butterfly, held firmly with smooth-tipped entomologists' forceps clasped across the fore and hind wings close to the body, objects very little to light strokes of the pen, and the alcoholic ink dries quickly

For the designation of a family from a single mating, that is, the progeny of one female, I use a small letter, reserving the corresponding large letter for the original wild female The individuals of each family as they pupate, or, if more convenient, as they emerge from the chrysalis, are marked with arabic numerals written at the right of the family letter, like an exponent In butterflies of course these numbers may run up to over 100 In one family of *Colias philodice* that I raised during the season of 1910 there were 128 brothers and sisters Suppose this family were the offspring of the wild female, "A," and were called "a" The last to pupate (or to emerge) would be "a^{128}" To facilitate the handling and recording of large families, it is sometimes well to raise the successive batches of eggs laid by a single female separately, designating each successive lot with a numeral written as a coefficient, so that $2n^{10}$ would mean the tenth butterfly to pupate (or to emerge) in the second lot of eggs laid by the mother of family "*n*" The name and pedigree of this female, and that of her mate, would be recorded, of course, at the head of the sheets on which the dates of pupation and eclosion of their offspring are set down.

No elaborate outdoor quarters are needed for keeping and mating live butterflies. The air of the laboratory needs only to be fresh and fairly moist, as that of the ground-floor rooms of large buildings of brick or stone is likely to be in summer The parched air of a steam-heated room, or of one upon an upper floor and flooded with direct sunlight, is more fatal to butterflies than complete absence of food in a moist atmosphere Bottomless cages 15 inches in length and breadth and 10 inches high, consisting of a simple frame of pine strips covered inwardly with cotton mosquito netting, are of ample size for *Colias philodice*, serving as a vivarium for the pupæ, as an enclosure for mating, and as a cage for the female during egg-laying, if the food plant is small enough to be covered by a frame of this size The use of wire screening is not to be recommended for adult butterflies, as it soon wears out and disfigures the wings that beat upon it A frame of this sort covered with cheese cloth, or better with the material known by milliners as frame covering, makes an excellent breeding cage for even the youngest larvæ.

The imago that has just crawled up from its chrysalis rests until the blood flows from the abdomen into the tiny pupal wings In *Colias philodice* this requires about five minutes, but the wings after reaching full size remain limp for about a half hour, and marking should be deferred until they harden Then the males of each family may be placed together in one cage, the females in another On the day following eclosion they will be ready to feed, and bouquets moistened with a solution of honey and water, or brown sugar, should be placed in the cages

It is surprising to a beginner to see how readily live butterflies may be handled in the absence of direct sunlight or intense diffuse light. Even out of doors, after sunset or in the early morning, they may be allowed to creep upon the finger wet with sweetened water, and feed They are attracted by a warm moist hand, as by a flower, and on holding them by the costal margin of the wings with one hand, and allowing them barely to touch with the feet a moist finger or palm of the other, they may be stimulated to extend the tongue and begin feeding Once feeding has begun, they may be moved to a generous drop of honey and water and allowed to drink their fill. In dull, cold weather butterflies neither feed nor lay, and it is necessary in midsummer, when metabolism is rapid, that

individuals to be used in breeding should have at least one square meal a day, served either in the early morning or evening, when they can be handled without danger of escape. In case they are actively flying during the day, and visit the moistened bouquet provided for them, they will of course feed themselves, but they are more strongly attracted toward the source of light than toward food, so that, if only slightly active, they may not reach the food supply at all. This is one reason against the use of large cages. They do not go in search of food, as the bee seems to do, but, stimulated by light to activity, they find it almost by accident. Hence they must be kept near the food.

The same reason applies to the use of small cages for mating. The larger the cage, the smaller are the chances that two individuals will meet. I began my experiments by turning butterflies loose in a large screened veranda, strongly lighted only on one side. Under such conditions their attraction towards the light absolutely controlled them. Each went his or her own way, paying not the slightest attention to the others. If several males and females of the same species are placed in a cage of the dimensions noted above (10 inches high and 15 inches square) or 15 inches in all three dimensions, and kept in the direct sunlight, or, if the temperature is high enough, in strong diffuse light, some matings may be expected. As soon as a couple are mated they should be removed to a separate cage, and their numbers noted. Mating continues in *Colias philodice* for over an hour, usually for about an hour and a half, and often two or three hours, so that there is little danger of promiscuity when large numbers of both sexes are placed in the same cage, if properly watched. One male often can be mated on successive days with several females.

Fertilized females often begin to lay on the day after mating. They will lay quite well indoors under warm, sunny conditions, provided they are well-fed, but in any case the food plant on which they lay should be growing, so that the minute larvæ, upon hatching, will find fresh food awaiting them. The most convenient way to obtain the eggs and rear the larvæ of *Colias philodice*, for example, is to place the butterfly in a cage over healthy clover growing on a lawn that is free from ants and slugs.

The food plants and feeding habits of larvæ are so varied that few general directions can be given for their care. Caterpillars that feed on coarse leaves that wilt slowly when gathered may be kept in large, flat, cloth boxes, like those that are used at the Gypsy and Browntail Moth Laboratory at Melrose Highlands, Mass. But the leaves of most food plants of butterflies soon become wilted and dry under such conditions, and it is preferable to enclose the growing plant in a cage, or a branch of the shrub or tree in a bag of cheese cloth. If kept in close glass vessels to prevent evaporation, or even in large moist vivaria, there is danger in *Colias philodice*, at least, of infection with an intestinal bacterial disease that may kill a large proportion of both larvæ and pupæ. So a good general rule is to keep the larvæ upon their food plant out-of-doors, and well screened from insect parasites and birds.

Pupæ should be carefully guarded from mice and slugs, and if either are at all abundant the chrysalids should be taken indoors. *Limax maximus* will gnaw through a fine cloth netting on the inside of which a pupa rests, and eat the chrysalis, leaving a small hole through the screen, the margin of which is blackened with the salivary juices of the slug, which apparently contain sulphuric acid.

The student of the genetics of butterflies will hardly be content with the ordinary museum methods of mounting specimens upon pins stuck into cork. Greater compactness, perfect safety from museum pests, and quick accessibility to both surfaces of the wings are needed. The patent Denton mounts for individual specimens satisfy these requirements well, but they are expensive for use in large numbers and, though vastly superior to the ordinary pin-cushion method, are not convenient to handle when huge families are being examined and compared, because each specimen must be picked up separately. All these needs, however, are met by a simple form of

case which the present writer has used with much satisfaction

The mount consists of a rectangular, wooden frame of any desired size (e g, 10 × 12 inches) made of pine strips three eighths of an inch square in thickness, mitered or mortised at the corners, holding apart two sheets of glass corresponding in size to the outer edge of the frame, one for the top and one for the bottom of the mount, which is bound together with passe-partout 1¼ inch wide As for the glass, old photographic plates, 10 × 12 inches in size, cleaned with caustic potash solution, are convenient in dimensions, thin and light, and of good quality.

Each butterfly is prepared by stretching and drying it upon its dorsal surface, pinning it temporarily until it has been made fast with strips of paper. The wings of the dried specimen must lie flat, or be inclined slightly ventrad, but never dorsad It is then fastened, with a small drop of thin liquid glue applied to the dorsal surface of the thorax, to the sheet of glass that is used as the upper pane or cover Small strips of sheet lead (about 1 inch × 1½ inches), bent into an arch, make a convenient weight to set astride the wings until the specimen is well fastened to the glass. The pane is then inverted over the frame, and glued to it The lower sheet should not be glued to the frame, but fastened to it only by the strip of passe-partout, 1¼ inch wide, which is used to hold the two panes of glass together and seal the mount. If a specimen should get loose, the bottom glass may be easily cut away, repairs made, and the case sealed with fresh passepartout. If the upper pane should get broken, it is a simple matter to remove the specimens, using steam when necessary, and remount them. Care should be taken in the preliminary stretching of the specimens lest the feet should project more than necessary, so that, when the case is put together, they come into contact with the lower plate, and loosen the attachment to the upper. For ordinary purposes, however, it is only necessary to trim off the tips of a few that project excessively.

Seven hundred butterflies of the size of *Colias philodice* can be filed away in the space of a single cubic foot, in the mounting frames just described, each case measuring 10 × 12 inches in breadth and length and one half inch in thickness, and containing 25 specimens They are sealed from dust and vermin, and easily examined on both surfaces in groups of convenient size

A rich field for conquest awaits any one who chooses to leave the beaten tracks of entomology and scout among the fastnesses of experimental evolution When one considers the remarkable results that have been accomplished single handed by such observers as Standfuss, Tower, Doncaster and T H Morgan, not to mention many others, the possibilities achieved in this field if the huge army of observers already interested in insects should attack in an organized way the problems of variation, the inheritance of acquired characters, mutation and natural selection, polymorphism and sex, mimicry and protective resemblance, can hardly be overestimated Desultory observations of the strolling naturalist will not help much in this conquest, but long-continued breeding of carefully selected strains under well-controlled conditions can not fail to win valuable results

Entomological societies and journals of the future, in order to contribute effectively to the real advancement of science should organize cooperative plans of research along these lines, and enlist the services of the countless observers whose random notes now fill their archives

JOHN H GEROULD

VARIEGATION OF EUROPEAN ALFALFAS

As a part of the extensive investigations being conducted with alfalfa at the Dickinson, North Dakota Sub-station, a series of European alfalfas was planted in the nursery in 1909 A study of some of the plants in 1910 revealed the presence of variegation in flower coloring. This was expected to a certain extent As a preliminary to the determination of the correlation of the variegation to other characters, both physiological and morphological, the percentage of variegation was determined for each strain or planting

Variegation is a feature of certain alfalfas, which undoubtedly indicates that at some previous time at least one parent has been the yellow-flowered sickle lucern, *Medicago falcata*. The flowers of the pure *Medicago sativa* retain their original color from the time of blooming to the time of withering. The color may range from nearly white to some shade of violet, but the color, whatever it may be, remains stable during the period of bloom. The flowers of *M. falcata* are of a chrome yellow, and remain constant, as do the flowers of *M. sativa*. The flowers of the hybrids of these two plants show a range of coloration during bloom, before withering, which, in extreme cases, runs from rich pansy violet through lettuce-green to coppery-yellow. Even in plants having apparently but a small proportion of *falcata* parentage this variegation of color is retained, though in a manner much less pronounced than in the case instanced.

The alfalfas under experiment which are given below were secured through the United States Department of Agriculture. Many of them were obtained from abroad through the energy of Mr. Charles J. Brand, of that department.

The number at the left of each strain is the seed and plant introduction number of the Department of Agriculture. The names are the translations of the German common names, or in many instances, the locality whence the seed was obtained is alone given. The total number of plants of each strain and the percentage of variegation are given.

A supplementary table is given which groups the alfalfa strains according to their geographic origin or to the name borne by them in Europe.

Summarizing the foregoing table we have the following:

S. P. I. No.	Name and Source	Number of Plants	Per Cent Variegated[1]
25110	Commercial Sand Lucern (Switzerland)	22	72.7
25178	Commercial Sand Lucern (Bohemia)	39	64.2
25175	Old German Franconian alfalfa (Bavaria, Germany)	43	56.0
24667	Old German Franconian alfalfa (Bavaria, Germany)	46	54.4
25182	Eifeler lucern (Rhenish, Prussia)	13	54.0
25267	German alfalfa (Prussia)	35	51.5
24733	Old German Franconian alfalfa (Baden, Germany)	43	49.0
25184	Provence alfalfa (Germany)	15	46.6
24602	Provence alfalfa (Germany)	42	40.5
25194	Old German Franconian alfalfa (Bavaria, Germany)	32	40.5
25257	Pfalzer lucern (Baden, Germany)	28	39.4
24923	Old German Franconian alfalfa (Württemberg, Germany)	42	38.0
25269	Roumanian alfalfa (Southern)	36	36.0
24603	Commercial Sand Lucern (Erfurt, Germany)	42	35.8
24635	Old German Franconian alfalfa (Baden, Germany)	41	34.2
24740	Italian alfalfa (northern Italy)	42	33.4
25022	Old German Franconian alfalfa (Baden, Germany)	43	32.6
24721	Provence alfalfa (France)	35	31.5
24767	Old German Franconian alfalfa (Baden, Germany)	42	31.0
25183	Old German Franconian alfalfa (Baden, Germany)	13	30.4
25115	Commercial Sand Lucern (Bromberg, Prussia)	37	29.8
25091	Commercial Sand Lucern (Strasburg, Germany)	41	29.2
24727	German alfalfa (Baden)	44	27.3
24741	Commercial Sand Lucern (Bohemia)	44	27.3
24735	Italian alfalfa	38	26.2
23394	Commercial Sand Lucern (France)	34	26.2
25112	Commercial Sand Lucern (Switzerland).	24	25.0
24718	Moravian alfalfa (Bohemia)	43	23.3
25193	Old German Franconian alfalfa (Baden, Germany)	39	23.0
24728	German alfalfa (Baden)	44	22.7
25111	Commercial Sand Lucern (Switzerland)	22	22.3
24722	Provence alfalfa (France)	45	22.2
25268	Commercial Sand Lucern (Bohemia)	37	21.4
25176	Commercial Sand Lucern (Bohemia)	43	21.0
23481	Commercial Sand Lucern (Hamburg, Germany)	40	20.0
25167	German alfalfa (Thuringia)	41	19.5
25270	Roumanian alfalfa (northern)	36	19.4
24719	Hungarian alfalfa (Austria)	43	18.6
24717	Bohemian alfalfa (Austria)	44	18.3
24730	Russian alfalfa (southern Russia)	46	17.4

[1] At the time of determination of variegation the various rows were indicated by arbitrary numbers. The results were thus not biased by previous knowledge. The variegation was determined by the presence or absence of color change in the standards of the unwithered flowers. This was readily determined in most cases. But in any case, all plants were subjected to a practically uniform judgment.

SOCIETIES AND ACADEMIES

THE GEOLOGICAL SOCIETY OF WASHINGTON

At the 234th meeting of the society, held on Wednesday, November 30, 1910, the following papers were read

Regular Program

The Influence of Marine Currents on Deposition in Continental Seas E O Ulrich

This paper tends to prove that Mr. Bailey Willis's views in regard to non deposition in continental seas as the result of current action are in the main unfounded In brief, Mr Willis's views are that the numerous minor hiatuses in the geologic column are commonly to be attributed to non-deposition and even to submarine scour, resulting from marine currents, rather than to emergence of the sea bottom In preface brief allusions were made to instances of local thinning or absence of sediments that may be justly ascribed to current work It is doubtless true that marine currents flow at certain times through sub-marginal troughs like the Lævis channel

Arguments were brought against Willis's views under two headings, namely the improbability of the existence in Paleozoic continental seas of currents competent to bring about such results, and the lack of evidence of such action having taken place under conditions obviously the most favorable for the existence of such currents.

Currents of sufficient intensity to cause an appreciable interruption of deposition over wide interior areas could only exist in great seas, in which the admittedly necessary "trans-continental currents" of Willis might be developed Such seas have no foundation in fact At any given time the Paleozoic seas of North America were far less extensive than those delineated by Willis or even those depicted in Schuchert's "Paleogeography of North America" Such maps are synthetic, giving the maximum development of several successive seas The Black River—early Trenton submergence—having, as generally believed, the greatest areal development of any Paleozoic seas, may be taken as the extreme example. This submergence consisted of no less than five and possibly six distinct transgressions, as shown by the areal distribution of the successive faunas and of the beds containing them. These six faunas are sharply defined and any two juxtaposed faunas show clearly by the varying direction of the overlap of their containing formations that they invaded from quite different oceanic basins Moreover, no two of these faunas

could have been synchronous, since there is no evidence of intermingling of species characterizing the respective formations in the median areas of interfingering overlaps

It is only the pelagic and semi pelagic types that can be depended upon for exact correlation between widely separated areas, and prove the existence of unobstructed current highways Referring to such organisms, the distribution of the Eopaleozoic graptolites offers very strong arguments against the hypothesis of transcontinental currents in the interior basins The most important of the graptolite faunas are confined to current-swept submarginal channels Had these currents continued across the continental border, as assumed by Willis, the graptolites must have been carried by them into and through the interior seas, a condition wholly negatived by the evidence in hand

Perhaps the strongest argument against the efficiency of currents in preventing deposition in the interior continental seas is found in stratigraphic overlaps In any period of sea-advance, beds are deposited by overlap toward the "positive" or relatively elevated areas At the same time, the submergence increasingly favors the formation of currents If currents were present and competent to cause scour, phenomena quite opposed to those observed would obtain The lower beds, which are absent, should be present, and the later beds, formed in a sea supposedly favorable to the extensive development of strong currents, should not be deposited, or should show the effects of current action by diminished thickness

EDSON S BASTIN,
Secretary

THE GEOLOGICAL SOCIETY OF WASHINGTON

AT the 235th meeting of the society, held on December 14, 1910, Mr M R Campbell, the retiring president, presented an address, entitled "Historical Review of Theories Advanced by American Geologists Regarding the Origin and Accumulation of Oil."

At the close of Mr Campbell's address the eighteenth annual meeting of the society was held for the purpose of electing officers, and the following officers were elected for the ensuing year

President—Mr Alfred H, Brooks

Vice-presidents—T W Stanton and David White.

Treasurer—Hoyt S Gale

Secretaries—Edson S Bastin and Robert Anderson

Members at Large of the Council—W C Mendenhall, Wm C Alden, F C Schrader, F B. Van Horn, Adolph Knopf

FRANÇOIS E MATTHES,
Secretary

THE GEOLOGICAL SOCIETY OF WASHINGTON

THE 236th meeting of the society, held on Wednesday evening, December 21, 1910, in the Cosmos Club, was devoted entirely to a discussion of Mr E O Ulrich's paper entitled "The Influence of Marine Currents on Deposition in Continental Seas," delivered before the society on November 30, 1910

The discussion was opened by Mr Bailey Willis, who summed up the propositions from which he wished to dissent as follows (1) that the epicontinental seas of eastern North America during the Middle Ordovician age were so landlocked that marine currents could not have passed through them with sufficient force to have influenced the deposition of sediments, and could not have kept the bottom clean of sediment in any portion of the area which was submerged, (2) that the Gulf Stream does not go to the bottom of its channel and does not scour the bottom The first, which was brought forward by Mr Ulrich, he considered largely theoretical, and founded upon an interpretation of the distribution idea which has not sufficient support in the physical evidence of unconformities that must have been developed by subaerial decay and erosion upon exposed portions

Mr Willis recognized that there are areas characteristic of the shores of the Ordovician sea and of the shores of islands in that sea where unconformities may be recognized by the usual evidences of erosion, and also that there are other localities where limestones are wanting that are elsewhere developed to notable thicknesses In many of these partial sequences there is no evidence of exposure to subaerial agencies In these cases it is reasonable to consider the alternative proposition of marine scour as of at least equal value in interpretation with that of the former existence of land

In answer to Mr Ulrich's statement that the Ordovician seas were landlocked, he pointed out the evidence brought forward by paleontologists for the wide distribution of faunas composed of numerous species, and maintained that marine currents were the most effective agencies in promoting that distribution. Were the seas so land-

locked as Mr Ulrich supposed, the food supply would fail and the condition which has been reached by the present Black Sea whose waters are incapable of supporting life that in any way approaches that of the Ordovician, might be reached

Referring to the paleogeographic maps which have been issued by Dr Schuchert and to Mr Ulrich's views on the details of paleogeography in the Paleozoic age, Mr Willis held that no one is yet in a position to interpret the evidence for limited intervals of time The study requires the most searching investigation of the different lines of evidence and a better understanding of the principles that shall govern the interpretation before any more than general outlines of the geography can be mapped Dr Schuchert's maps represent the distribution of faunas, and for each fauna which is mapped they represent the extent of the temperature, food and other conditions that determined its habitat In this respect they are of the highest value Where, however, the absence of a fauna or a formation has been taken as a proof of the existence of land without evidence of erosion, the maps are misleading, since the alternative hypothesis that the area was submerged, but was inhospitable to that particular fauna, has not received due consideration The causes which now maintain the great equatorial currents flowing from east to west have been in operation since the oceans were established Currents and eddies diverted from these main currents by the continental platforms have necessarily been features of all continental seas, and no study of the life conditions of extinct faunas can be adequate that does not take account of the biological and physical effects of such currents Hence any inference based upon faunas which are interpreted without reference to currents must be fallacious

In regard to the subject of marine scour, especially by the Gulf Stream, Mr Willis presented a map showing the submarine deposits of the Caribbean, Gulf and North Atlantic, as given by Agassiz in the "Three Cruises of the *Blake*" That map shows that sediment is deposited under the axis of the Gulf Stream between Cuba and Florida along much of the coast, for the depth of the water is there greater than the depth of the current, which does not reach much below 100 or 150 fathoms, but where the water is shallower or where the current turns from its easterly to a northerly course, it is carried against the bottom and at those points there is a hard limestone bottom covered only by fragments of broken rock and coral, and washed clean by the current. It also appeared from Agassiz's discussion of the action of the dredge that the areas which he mapped as limestone plateaus have a hard and uneven rock bottom, and although the Coast Survey charts over much of the areas so mapped by him show soundings of sand and broken shell, the evidence is that the material brought up on the sounding line is but a superficial coating, hardly covering the uneven limestone bottom Admiral Pillsbury has shown that the volume of water passing a section of the Florida Straits in one hour amounts to nearly 90 billion tons It has a velocity which varies from two to three and one half knots The energy of this mass of water could not be lightly checked Should the sea bottom between Florida and Cuba be gently elevated by an orogenic movement, or should the general level of the ocean be lowered so that the current would reach the bottom, the silt which is now deposited beneath the current would inevitably be swept away A barrier to the current would only be established in case the orogenic movement raised the bottom more actively than the current could erode it This could scarcely occur unless the bottom were hard rock The condition which is thus suggested is that which may be considered as a working hypothesis in explanation of the imbricated limestone of the Ordovician in the eastern United States. It is postulated that there was an extensive sea which was open from south to north, and through which marine currents circulated, as is indicated by the distribution of life The sea deepened or shallowed from time to time, and there were basins which, according to the great thickness of sediments laid down in them, deepened, while other areas apparently remained as saddles between them. If this interpretation of the physical and faunal facts be correct, it is reasonable to suppose that the currents were at times brought within reach of the bottom and that a condition of non-deposition supervened locally during a more or less prolonged interval

The discussion was continued by Rear Admiral J. E Pillsbury, who had command of the Coast Survey steamer *Blake* for five years and spent a large portion of each year investigating the Gulf Stream He first explained the methods formerly used of gauging marine currents by cans floating on the surface and submerged below, and then the methods adopted by the *Blake* of anchoring the vessel in the stream and measuring the

velocity and direction of the flow on the surface and at various depths by means of a current meter Many hundreds of observations were taken in the straits of Florida between Fowey Rocks and the Bahamas, between Havana and the Florida reefs, in the Straits of Yucatan, in the Equatorial Current between Tobago and Barbadoes, in all the passages between the West Indian Islands and off Cape Hatteras

The section off Fowey Rocks was studied during two winter seasons and at other times for brief periods This is the narrowest part of the Straits of Florida, being about 42 miles in width On the west side the bottom descends with fairly regular slope to 400 fathoms, at 15 miles distant, while on the east side 400 fathoms is found at but eight miles from the shore Anchorages were made at approximately seven-mile intervals across the straits The bottom was found to be branch coral and broken shells at the anchorage nearest the Bahamas, and there was every evidence from the observations that the current reached the bottom here The stream off Havana flows east, while off Fowey Rocks it has changed its direction 80°, and the inertia of the water in making the turn forces the current to impinge upon the confining bank and carries it to the bottom Between this point and the western slope the observations showed an average current only to about 300 fathoms depth, while on the western slope itself the current sometimes reached the bottom and sometimes a negative current was observed At all anchorages except the easternmost, mud was brought up by dredge and frequently on the anchor. At eleven and one half miles east of Fowey Rocks there is an outcropping of rock on which an anchor fouled three times, making it necessary to cut the anchoring rope to get underway, but at other places the bottom was soft On both sides of the straits the current at times was found to be flowing north as far out as a depth of 10 fathoms or even further off shore

It has been stated that the presence of gulf seaweeds near Nantucket shows the Gulf Stream to be flowing there The Gulf Stream is partly caused by the friction of the trade-winds on the surface of the ocean, and partly by the break of the wave which throws a certain amount of water from its crest into the trough As the trades are persistent, this becomes a simultaneous movement of the whole surface of the sea within trade-wind limits. Gulf seaweed floats with the current, but it is thrown to leeward by the waves faster than any ordinary current can carry it, or when there is no current at all The water on the Florida reefs about Key West are of milky appearance, while a northerly breeze is blowing which stirs up the bottom coral mud A southerly breeze brings in the clear water of the Gulf Stream simply by the break of the waves, but no current accompanies it

The Grenadine Bank extends from Grenada to the Island of St Vincent and is in the direct line of flow of the trade wind current outside the Caribbean An anchorage in 17 fathoms near its outside edge showed no current crossing the bank, but the break of the waves was all the time carrying water into the Caribbean across the shoal

As the discussion was extended to a consideration of the general effects of oceanic currents on deposition, Mr T Wayland Vaughan called attention to the investigations Rear Admiral Sir W J L Wharton[1] made around the islands of the Ellice Group and on submarine banks in that region According to this authority, fine mud and sand may be moved to a depth of 80 fathoms, and there is evidence of the chafing of cables to a depth of 260 fathoms, "volcanic ash can be moved at depths of 30 fathoms or more when exposed to the action of waves in an otherwise deep sea over which strong winds are continually blowing"

Professor J Stanley Gardiner[2] has described the submarine platform on which the Maldive and Laccadive archipelagoes stand, and has called attention to the generally hard bottom on it This platform occupies a level about 200 fathoms below sea level, and he says, "there is little doubt but that it is surrounded with precipitous walls or a steep slope for an additional 600 fathoms at least" Professor Gardiner is of the opinion that this platform was formed by marine erosion to the depth of 200 fathoms below sea level. He states, "there is little doubt but that currents may extend to considerable depth and sweep the ocean floor quite bare. Indeed, wherever in the ocean a rocky bottom is found, its character is probably due to an ocean current"

Dr Paul Bartsch discussed the distribution of the recent marine mollusks with a view to throwing some light upon past conditions He presented a map showing the extent of the existing faunal areas and called special attention to the

[1] *Nature*, LV, 1897, "Foundations of Coral Atolls"

[2] "The Fauna and Geography of the Maldive and Laccadive Archipelagoes," Vol 1, Pt. 2, pp 172, 173.

fact that these areas are coextensive with the existing ocean currents

He gave some tables, based upon the West American Pyramidellidæ, showing that in this group a remarkably small percentage of the species extended over more than one area He stated that he considered ocean currents an important factor in the distribution of marine organisms, since they determined practically all the factors entering into the environment in each area, viz, temperature, food, salinity and transportation of larval forms

Mr Ulrich, replying to Mr Willis's discussion, said that most of Mr Willis's objections had been anticipated and accounted for in the paper read at the previous meeting It was denied that this paper contained any statement indicating that its author is inclined to the belief that marine currents in the Ordovician epicontinental seas of North America were *never* capable of effecting the deposition of sediments or of keeping the "bottom clean of sediment in any portion of the submerged seas" On the contrary, Mr Ulrich mentioned a number of instances of locally interrupted deposition attributable to current scour but claimed that these were quite distinct in their causation from the wider discontinuities which have been similarly interpreted by Mr Willis It was further denied that the paper sought in any wise to discredit the effect of currents on the distribution of marine organisms Also that the deduction of frequently shifting, limited and far from transcontinental seas is founded solely on "an interpretation of the distribution of faunas which disregards all the limiting conditions of marine environment except land barriers" Mr Ulrich insisted that before reaching his conclusions he had considered more or less fully all physical as well as the purely faunal criteria that seemed to have any direct bearing on the problem Considering that Mr Willis has paid perhaps as little attention to detailed field investigation of stratigraphic unconformities as to the study of recent or fossil zoology, his short dismissal of conclusions based largely upon such studies as "purely theoretical" seems rather unscientific His remark respecting detailed paleogeographic mapping, when he said "that no one is yet in a position to interpret the evidence for limited intervals of time" is similarly unjust

Mr Willis's statement that the Ordovician seas, "if so land locked as Mr Ulrich supposed," would have become, like the Black Sea, "incapable of supporting life that in any way approaches that of the Ordovician," was based upon a misconception of Mr. Ulrich's meaning As conceived by Mr Ulrich, Ordovician continental seas invaded the land areas from one or another of the permanent oceanic basins, with which they maintained their connection and from which they derived their faunas throughout their existence

Evidence of erosion is nearly always to be found wherever a considerable hiatus in the stratigraphic sequence is indicated by the fossils. In view of the fact that such breaks in the stratigraphic sequence commonly extend over by far the greater part of the median area of the continent, it is impossible to account for the wide absence of the deposits and faunas by virtue of any reasonably conceivable current efficiency Nor can any other interpretation save emergence be advanced to explain the established geographic limitations of the Paleozoic faunas, especially when no fauna of nearly similar age is found in adjacent areas

The distribution of many types of littoral and bottom-dwelling organisms takes place largely in disregard of marine currents There are other types, however, notably the plankton and especially reef corals and sessile bryozoa, which propagate by means of free-swimming larvæ, that throw much light on the direction and extent of the currents in the Paleozoic continental seas In every case where the distribution of the latter has been studied it is found that they rapidly become fewer away from the point of invasion of the particular sea in which they lived In most instances they disappear entirely before reaching the inner shores of the sea whose extent is determined by continuity of deposits and the presence of other organisms less dependent on currents for their migration This perfectly competent evidence, therefore, is invariably opposed to Mr Willis's theory of great inland seas and of transcontinental currents which if present might have been important factors in accounting for stratigraphic hiatuses

Dr R. S Bassler called attention to the fact that the trend of the discussion was losing sight of the stratigraphic side of the question These distinct northern and southern faunas occurred in distinct formations overlapping to extinction either to the south or north as the case might be. He added that these facts must be explained before currents can be held accountable for the great faunal differences

UNIVERSITY REGISTRATION STATISTICS

THE registration returns for November 1, 1910, of twenty-seven of the leading universities of the country will be found tabulated on the following page Four institutions exhibit a decrease in the grand total enrollment this year, viz, Harvard, Iowa, Indiana and Virginia, as against four institutions in 1909, two in 1908 and five in 1907 The largest gains in terms of student units, including the summer session attendance, but deducting summer students who returned for work in the fall, were registered by Columbia (with an unprecedented increase of 1,279 students), California (674), Minnesota (621), Wisconsin (500), Chicago (396), Northwestern (346) and Pennsylvania (330). Last year there were also seven institutions that showed a gain of over three hundred students each, but only one (Columbia) that registered an increase of over four hundred students Omitting the summer session attendance, the largest gains have been made by Columbia (796), Minnesota (621), California (496), Wisconsin (407), Northwestern (379), Nebraska (236) and Chicago (231), seven universities exhibiting an increase of over two hundred students in the fall attendance, as against eleven last year, and it will also be observed that only one of the seven is an eastern institution, whereas the eleven last year were fairly evenly divided between the east and the west

According to the figures for 1909, the twenty-eight universities included in the table ranked as follows: Columbia, Harvard, Chicago, Michigan, Cornell, Pennsylvania, Illinois, Minnesota, Wisconsin,

* Includes schools of mines, engineering, chemistry and related subjects.
† Included elsewhere.
‡ No figures furnished.
Note.—The Texas and Tulane figures for 1903–1906 are exclusive of the summer session.

California, New York University, Nebraska, Yale, Syracuse, Northwestern, Ohio State, Missouri, Texas, Iowa, Indiana, Kansas, Tulane, Stanford, Princeton, Western Reserve, Washington, Virginia, Johns Hopkins. Comparing this with the order for 1910, we note that Chicago and Michigan have passed Harvard, that Pennsylvania has changed places with Cornell, that Illinois has been passed by Minnesota, California and Wisconsin, that California and Wisconsin have changed places, that Northwestern has passed Yale and Syracuse, that Kansas has outstripped Iowa and Indiana, as Tulane and Indiana have Iowa, and, finally, that Johns Hopkins and Virginia have changed places. For the first time in the annals of American universities the seven thousand mark has been passed, Columbia having a grand total registration this year of 7,411 students, a figure that will closely approach the eight-thousand mark before the end of the academic year. Pennsylvania is the sixth institution to pass the five-thousand mark, Cornell passed it in 1909, Chicago and Michigan in 1908, Columbia in 1907 and Harvard somewhat earlier. If the summer session enrollment be omitted, the universities in the table rank in size as follows: Columbia, Minnesota, Michigan, Pennsylvania, Harvard, Cornell, Illinois, California, Wisconsin, New York, Northwestern, Nebraska, Yale, Syracuse, Chicago, Ohio State, Missouri, Kansas, Texas, Iowa, Stanford, Princeton, Indiana, Western Reserve, Tulane, Johns Hopkins, Virginia, this order also showing a number of changes as compared with 1909, notably the advancement of Minnesota from seventh to second place.

Examining the various faculties in order, we find that the usual gains in the male undergraduate academic departments continue, the total increase being one of approximately a thousand students, it is impossible to calculate the increase with absolute accuracy, owing to constant changes of classification. On the other hand, it is noteworthy that the number of undergraduate women shows a decrease at the majority of the institutions in the list—quite an unusual condition. Harvard continues to lead in the number of male academic students, being followed by Michigan, Yale, Princeton, Wisconsin, Chicago, Columbia, Cornell, Minnesota, including the women, the order is Harvard, Michigan, California, Wisconsin, Minnesota, Chicago, Syracuse, Columbia, Yale, Princeton, Texas and Kansas, each of these institutions enrolling over one thousand academic students.

The number of scientific students is considerably smaller than it was last year, more than half of the institutions showing a loss compared with 1909. The chief gains were made by Illinois, Yale and Columbia, in the order given. The institutions that attract over five hundred students to their engineering schools are Cornell, which continues to maintain its old lead in this field, Michigan, Illinois, Yale, Wisconsin, Pennsylvania, Ohio State, California, Columbia, Minnesota, Missouri and Nebraska, in the order named, the first four universities mentioned enrolling over one thousand students each.

As was the case last year, there has been a decrease in the number both of medical and law students, this being due in the majority of the instances to a raising of the requirements for entrance to these professional schools. The largest gains in medicine have been registered by Western Reserve, California and Johns Hopkins, in law by Stanford, Columbia and Harvard, the largest losses in the former have been experienced by Northwestern, Pennsylvania and Iowa, in the latter by Virginia,

Yale and Texas Illinois now attracts the largest number of medical students, followed by New York University, Northwestern, Pennsylvania, Tulane, Johns Hopkins, Michigan and Columbia, each of these institutions enrolling more than three hundred students In law, Harvard and Michigan have passed New York University, these being followed by Minnesota, Columbia and Pennsylvania, the six institutions mentioned being the only ones in the table to attract over three hundred students.

Sixty per cent. of the graduate schools show an increase over last year's enrollment, and where losses are registered, they are slight Columbia, Stanford and Illinois exhibit the largest gains, the first named institution, with an enrollment of 1,167 non-professional graduate students, having more than twice as many as the next largest, Harvard (456), which is followed in turn by Chicago, Yale, Pennsylvania, California, New York, Cornell, Illinois and Wisconsin, each of these institutions enrolling more than two hundred students Over two thirds of the students enrolled in these eleven universities are to be found in eastern institutions

All of the schools of agriculture continue to show a highly encouraging increase, Minnesota remaining at the head of the list, while Cornell has passed Illinois — Of the architectural schools Cornell and Syracuse show slight losses, the others having registered an increase, especially Illinois and Columbia The four largest schools are Illinois, Pennsylvania, Columbia and Cornell, in the order named, the two latter having changed places since the last year —The largest schools of commerce are those of New York University, Pennsylvania and Northwestern, and all of these show very considerable gains in attendance over last year Wisconsin and California have also increased their enrollment in this field, while Illinois and the Harvard graduate school of business administration have remained stationary With the exception of Iowa and Tulane, all of the dental schools have increased their attendance, Northwestern, Illinois and Harvard showing the largest gains The institutions continue to rank in the order Pennsylvania, Northwestern, Michigan, Minnesota, in this department —Of the four divinity schools, Harvard alone shows a gain, the order in point of size being Northwestern, Chicago, Yale, Harvard — At all of the institutions where the students of forestry are listed separately, a gain is apparent —In the department of music, half of the institutions show a decrease in the number of students, this being especially large in the case of Northwestern and Wisconsin Syracuse, Nebraska and Northwestern continue to have the largest schools —In the department of pedagogy Minnesota, Missouri and New York University have suffered losses in attendance, while the other universities registered gains, especially the Teachers College of Columbia University, which exhibits an increase of no less than 432 students, it being by far the largest school of education in the country It is followed by New York University, Chicago and Missouri, in the order named —There has been a slight gain in the total number of students of pharmacy, the largest decrease having been experienced by Northwestern, the largest increase by Western Reserve, the other institutions being about evenly divided in the matter of gains and losses The three largest schools continue to be Columbia, Northwestern and Illinois —Ohio State, which has the largest school of veterinary medicine, has registered a loss of 21 students, Pennsylvania, which comes next, has

remained stationary, and Cornell and New York University have made slight gains

The summer sessions are enjoying continued prosperity, especially noteworthy gains having been experienced by Columbia (664), Pennsylvania (240), California (232) and Tulane (184), while Harvard registered a decrease of 504 students The only other decrease of moment was experienced by Northwestern, where the summer session in medicine has been abandoned, Iowa, New York University, Syracuse and Texas show slight losses, while Indiana, Michigan, Minnesota, Ohio and Stanford have remained practically stationary Chicago continues to assemble the greatest number of summer students in its summer quarter, Columbia's summer session is rapidly nearing the three-thousand mark, while Wisconsin, Michigan, Indiana and California have over a thousand students each Then come Cornell, Tulane, Harvard, Pennsylvania and Illinois, in the order named

Of the New England colleges for men included in the following table, Dartmouth, Tufts, Wesleyan and Williams show gains over last year, Amherst and Bowdoin losses Brown also shows a loss, as do Bryn Mawr and Mt Holyoke, while Smith, Vassar and Wellesley have more students than last year Massachusetts Institute of Technology, Lafayette and Oberlin have gained, Haverford, Lehigh and Purdue lost —At Amherst the introduction of a group system of electives, as well as the inauguration of a one-half-year rule in public exhibitions, may have had some effect on the diminution in size of the entering class —At Brown 657 of the college students are men, 199 women, and there are 74 graduate students enrolled.—At Bryn Mawr there are 69 graduate students. During the year 1909–10 this college received gifts amounting to $694,000.

Institution	1910	1909	1908	1904
Amherst	502	526	528	412
Bowdoin (incl med)	398	419	420	363
Brown (incl graduate school)	930	974	993	988
Bryn Mawr (incl graduate school)	409	412	393	441

Wesleyan	365	343	322	305
Williams	541	528	487	443

—At Dartmouth 1,144 students are registered in the college, 43 in the engineering school, 41 in medicine, 34 in the Tuck school of commerce and administration, and 21 are graduate students There were also 151 students enrolled in the summer school of this institution, of whom 47 returned in the fall, giving a grand total of 1,333 students Dartmouth has just completed a new gymnasium building, while an administration building is being erected for the college offices only —Haverford College is completing a new science hall, principally for chemistry, and has received a donation from an alumnus for a building for the Haverford Union The college has also introduced a pension system, for which a fund of $150,000 has been raised —At Lafayette College 77 students are enrolled in the classical course, 135 in the Latin scientific, 45 in the general scientific, 47 in the chemical, 89 in the civil engineer-

ing, 55 in the electrical engineering, 34 in the mining engineering and 14 in the mechanical engineering course.—Lehigh University has 540 engineering students, 48 in the college, and 28 graduate students. The physical equipment of the university has been materially strengthened by the erection of two new laboratories—the Fritz engineering laboratory and the Eckley B. Coxe mining laboratory, the former is devoted to tests in strength of materials, cement and concrete, hydraulics and road materials, the latter to experimental ore-dressing. Both laboratories are equipped with the most modern machinery and apparatus. Four new four-year plans of study leading to the degree of bachelor of science are offered by the university in the department of arts and science, *viz.*, one in which the biological and chemical sciences predominate, one in which the geological sciences predominate, one in which the mathematical and physical sciences predominate, and one in business administration.—At the Massachusetts Institute of Technology German has been made a required subject for all first-year students with the exception of the architects, who are required to take French; previously all first-year students could choose between German and French. Of the 1,506 students enrolled at the institute this winter, 107 are in the school of architecture. There were also 239 students in attendance on the 1910 summer session, of whom 175 returned in the fall, giving a total enrollment for the year of 1,570.—At Mount Holyoke College a dormitory, accommodating about twenty-five persons, has been added during the summer.—The total fall registration of Oberlin College is 1,826, divided as follows: college of arts and sciences 998, theological seminary 65, conservatory of music 406, academy (preparatory) 315, drawing and painting (college and preparatory) 42.—The students at Purdue University are distributed as follows: school of science 162, chemical engineering 80, civil engineering 334, electrical engineering 390, mechanical engineering 306, graduate students 30, agriculture 262, and pharmacy 74. The entrance requirements for the school of pharmacy have been raised to correspond to those of all the other departments of the university, namely, four years of preparation in a standard high school, the increase in requirements having led to a twenty five per cent. decrease in enrollment. An increase of no less than forty per cent. was registered in the freshman class of the school of agriculture. There has also been an appreciable increase in the number of women students, due to growth in the department of household economics. A notable addition to the resources of the university consists of the erection of a new group of buildings for the department of shop practise and drawing, comprising some 70,000 square feet of floor space with modern equipment.—At Smith College it is the object of the authorities at present to keep the enrollment as near 1,600 as possible, this being done by limiting the size of the entering class.—The total enrollment of Tufts College consists of 1,141 students, divided as follows: college, 111 men and 84 women, engineering schools 238, medicine 388, graduate students 7, dentistry 303, and divinity 10.—At Wellesley College there are 1,290 regular undergraduate students, 57 special students and 31 graduate students. Two new buildings have been added to the equipment, namely, a library and a gymnasium (Mary Hemenway Hall).—Of the 365 students at Wesleyan, 9 are women and 7 are graduate students.—At Williams 9 of the students are candidates for the degree of master of arts. A new infirmary and a

new auditorium are in process of construction and a new dormitory will be commenced soon This is the first year in which no "partial course" freshmen have been admitted, all those that entered being candidates for the degree of bachelor of arts[1]

RUDOLF TOMBO, JR

COLUMBIA UNIVERSITY

SUMMARY OF THE FIFTH ANNUAL REPORT OF THE CARNEGIE FOUNDATION[1]

THE fifth Annual Report of the President of the Carnegie Foundation covers the year ending September 30, 1910 The report is divided into two parts Part I pertains to the current business of the year, Part II is a discussion of the Relation of the College and the Secondary School

The report shows that the trustees had in hand at the end of the year funds amounting to $11,114,056 86, consisting of the original gift of $10,000,000 par value of five per cent bonds and one million accumulated surplus The income for the year was $543,881 20 During the year 64 retiring allowances were granted, of which 46 were in accepted institutions and 18 in institutions not on the accepted list During the year 23 pensioners died

Among distinguished teachers who retired during the year were Professor Burt G Wilder, of Cornell, Dean Van Amringe and Professor Chandler, of Columbia, both well advanced in years and in academic honors, Professor George L. Goodale, the famous botanist of Harvard, Professor Osborne, of the Massachusetts Institute of Technology, who has taught mathematics in that institution since its foundation, Chancellor MacCracken, of New York University, President Seelye, of Smith College, and Professor Calvin M. Woodward, of Washington University, St Louis These distinguished men average in age seventy-two years, and illustrate how well the vigor and influence of the scholar can be continued to a ripe maturity

There were admitted to the accepted list during the year the University of California, the joint institutions of the State of Indiana —Indiana University and Purdue University —and Wesleyan University, the last named a college

In the first part of the report the president of the foundation follows up the bulletin on medical education by a paper on the relation of the university to the medical school, in which he calls attention to the responsibility attaching to any college or university which undertakes medical education

The second part of the report is a careful attempt to state the existing causes of friction between the secondary school and the college, and the loss of educational efficiency in the present methods of bringing pupils from the school to the college The complaint of the college against the secondary school and the complaint of the secondary school against the college are set forth

An extremely interesting part of the report is a statement of the observations of Oxford tutors upon the preparation of the Rhodes scholars The strong points in the American boy's preparation are readily seen by these trained teachers, and the weaknesses which they find point directly to the superficiality and diffusion of the work done in the American secondary school and college

The president of the foundation urges that this whole question be approached by secondary school men and college men in a spirit of cooperation Neither the certificate method of admission nor the piecemeal examination method have, in his opinion, solved the problem He urges that the college must find a solution which will test better than the certificate or the piecemeal examination the fundamental qualities of the student, and which will at the same time leave to the high school a larger measure of freedom. He recommends a combination of certificate and examinations, the latter of simple and elementary character, but calling for a high quality of performance

[1] An abstract of this article appeared in the *Evening Post* (New York) of February 11

[1] Press bulletin supplied by the foundation

without which the candidate will not be admitted. For example, under this plan the boy who can not write good idiomatic English would not be admitted to college at all, but would be sent back to the secondary school. The entrance requirements recently adopted at Harvard are quite in line with these recommendations. The president of the foundation urges a cooperation between the secondary school and the college not as unrelated institutions, but as two parts of a common system of education. He argues that the interest of the great mass of high school students must not be sacrificed to the interest of the minority who are looking toward college. He insists on a larger measure of freedom for the secondary school, but on the other hand, he argues that the interest of the boy who goes to college and the boy who goes from the high school into business are alike conserved by learning a few things well, not by learning many things superficially. The boy who has obtained such intellectual discipline is a fit candidate for college, whether he has studied one set of subjects or another; without this intellectual discipline he is unfit alike for college or business. It is therefore, in the opinion of the president of the foundation, the plain duty of the college, at the present stage of American educational development, to articulate squarely with the four-year high school and to leave the secondary school the largest freedom so that it may educate boys, not coach them, but at the same time to require of the candidates for admission tests which rest upon high performance in the elementary studies and which mean mastery of the fundamentals. In such a program lies the hope of scholarly betterment and of civic efficiency for both college and high school.

The report may be obtained by writing to The Carnegie Foundation, 576 Fifth Avenue, New York City.

THE PUBLIC HEALTH SERVICE

The following bill has been introduced in the senate and in the house of representatives:

A Bill To change the name of the Public Health and Marine Hospital Service to the Public Health Service, to increase the pay of officers of said service, and for other purposes.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the Public Health and Marine-Hospital Service of the United States shall hereafter be known and designated as the Public Health Service, and all laws pertaining to the Public Health and Marine-Hospital Service of the United States shall hereafter apply to the Public Health Service, and all regulations now in force, made in accordance with law for the Public Health and Marine Hospital Service of the United States shall apply to and remain in force as regulations of and for the Public Health Service until changed or rescinded. The Public Health Service may study and investigate the diseases of man and conditions influencing the propagation and spread thereof, including sanitation and sewage and the pollution either directly or indirectly of the navigable streams and lakes of the United States, and it shall from time to time issue information in the form of bulletins and otherwise for the use of the public.

Sec. 2. That beginning with the first day of July next after the passage of this act the salaries of the commissioned medical officers of the Public Health Service shall be at the following rates per annum: surgeon general, $6,000; assistant surgeon-general, $4,000; senior surgeon, of which there shall be ten in number, on active duty, $3,500; surgeon, $3,000; passed assistant surgeon, $2,400; assistant surgeon, $2,000; and the said officers, excepting the surgeon general, shall receive an additional compensation of 10 per cent. of the annual salary as above set forth for each five years' service, but not to exceed in all 40 per cent.: Provided, That the total salary, including the longevity increase, shall not exceed the following rates: assistant surgeon general, $5,000; senior surgeon, $4,500; surgeon, $4,000: Provided further, That there may be employed in the Public Health Service such help as may be provided for from time to time by Congress.

SCIENTIFIC NOTES AND NEWS

At a meeting held on January 12 the Geological Society in Stockholm, Sweden, elected to eight vacancies in their twenty corresponding memberships, Frank D. Adams, Montreal; Charles Barrois, Lille; Eduard Bruckner, Vienna; Albrecht Heim, Zurich; C. R. van Hise, Madison; James F. Kemp, New

York, Albrecht Penck, Berlin, and Charles D Walcott, Washington

DR W J. HOLLAND, director of the Carnegie Institute, Pittsburgh, has received from the Czar of Russia, the insignia of a knight of the order of St Stanislas, second class, in recognition of his services to science, and Mr A S Coggeshall, the chief preparator in the section of paleontology in the same institution, has had conferred upon him by the same sovereign knighthood in the order of St Anne

DR HENRY PRENTISS ARMSBY, director of the Institute of Animal Nutrition of the Pennsylvania State College, has been elected a member of the Royal Society of Arts of Great Britain.

DR H. LORENZ, professor of physics at Leyden, and Dr E Strasburger, professor of botany at Bonn, have been elected members of the St Petersburg Academy of Sciences

DR HENRY FAIRFIELD OSBORN, president of the American Museum of Natural History and Da Costa professor of zoology at Columbia University, was given a dinner by his former students at the Faculty Club of Columbia University, on February 18, in celebration of his thirtieth anniversary as a teacher About forty-five guests and former students under Professor Osborn at Columbia and Princeton Universities were present Speeches were made by Professors E B Wilson, W B Scott and C F W McClure

DR. HENRY M HURD has retired from the superintendency of the Johns Hopkins Hospital, and is succeeded by Dr W H Smith, superintendent of Bellevue Hospital, New York City

DR ANDREW W PHILLIPS, since 1891 professor of mathematics in Yale College and since 1895 dean of the graduate school, will retire from active service at the close of the present academic year.

CHARLES JOYCE WHITE, professor of mathematics at Harvard University from 1885 to 1894, has been appointed emeritus professor, and William Barker Hills, associate professor of chemistry from 1889 to 1904, has been appointed emeritus associate professor

THE University of La Plata and the University of Michigan have arranged for cooperation in the work of their astronomical observatories Professor W J. Hussey has been appointed director of La Plata Observatory, but is still to remain director of the observatory of the University of Michigan He will divide his time equally between the two institutions, spending the second semester of each year at Ann Arbor Mr R P Lamont, of Chicago, is furnishing a 24-inch refracting telescope for the University of Michigan It is the intention to take this instrument, when completed, to a favorable site in Argentina, and while it is there to have it used under the joint auspices of the two universities

PROFESSOR GILBERT N LEWIS, of the Massachusetts Institute of Technology, will deliver eight lectures on "The Principle of Relativity," on Monday and Thursday afternoons, beginning on March 6, in the Jefferson Physical Laboratory of Harvard University

UNIVERSITY AND EDUCATIONAL NEWS

IN the Massachusetts senate on February 21 the committee on education reported a resolve, on the petition of Richard C Maclaurin, president, and others, for an increase in the state appropriation for the Massachusetts Institute of Technology The resolve provides that there shall be paid annually, for ten years, to the institute the sum of $100,000, from January 1, 1912, to be expended under the direction of the corporation for the general purposes of the institute, the institute shall maintain forty free scholarships in addition to those already maintained

MR CARNEGIE recently wrote the board of trustees of the Carnegie Instituta that he is prepared to increase the endowment income $50,000 or $100,000 a year if it can be shown that any department is hampered from lack of funds The founder expects to visit Pittsburgh about May 1 to receive the report of the board.

AN alumnus, who wishes to remain anonymous, has given to Phillips Exeter Academy $18,744, with which to complete the Wentworth mathematical fund of $50,000 William

A Francis has been elected the first Wentworth professor of mathematics He has been professor of mathematics since 1892

THE Ohio house has passed the Cahill bill, which had previously passed the senate, providing for the compulsory teaching of agriculture in the common schools of villages and townships

ON February 15 and 16, about one hundred and sixty members of the Illinois general assembly went to the University of Illinois to make their biennial inspection A convocation was held in the auditorium, at which time addresses were given by various members of the house and senate In the afternoon a conference with members of the appropriation committee and heads of the departments was held, at which time the needs of the university were presented The university is requesting from the legislature this year for maintenance and general equipment $2,201,000, also for new buildings, the sum of $1,150,000, for maintenance of the College of Medicine, $200,000 In addition to these requests it also is supporting the request of the College of Agriculture for $1,575,750 for maintenance and equipment In addition to the above the mining interests of the state are supporting a bill proposing an appropriation of $240,000 for the construction of the mining engineering building and maintenance of the department of mining engineering. The ceramic interests are likewise supporting a bill proposing an appropriation of $45,000 for the department of ceramics

DR JOHN G BOWMAN, secretary of the Carnegie Foundation, has been elected president of the Iowa State University to succeed Dr. George E MacLean

THE Rev. Dr George Edward Reed has resigned the presidency of Dickinson College after twenty-two years of service.

RECENT appointments in the School of Mines of the University of Pittsburgh are Dr Charles R Eastman, of Harvard University, as professor of paleontology, Otto Emery Jennings, of the Carnegie Museum, as instructor in paleobotany, and James Z Zimmerman as assistant in mining Mr George T Haldeman, instructor in mining, has recently been appointed superintendent of the Mine Rescue Work of the Lehigh Valley Coal Company and Mr Edward L Estabrook, assistant in mineralogy, has been appointed instructor in petrology at Lehigh University

PROFESSOR VICTOR R GARDNER, head of the department of horticulture at the University of Maine, has accepted the appointment of associate professor of pomology at the Oregon Agricultural College, to succeed Professor C A Cole, who has resigned to take up industrial work

ERNEST GALE MARTIN, Ph B (Hamlin), Ph D (Johns Hopkins), has been promoted to an assistant professorship of physiology at Harvard University

DR TH PAUL, professor of chemistry at Munich, has been appointed director of the laboratory of inorganic chemistry at Leipzig, to succeed Professor Ernst Beckmann

DISCUSSION AND CORRESPONDENCE

THE AIR WE BREATHE IN BUILDINGS

TO THE EDITOR OF SCIENCE Two or more years ago my attention was drawn to the astonishing and unfortunate condition of the throats and tonsils of school children and the number of children who had adenoids This led, through a series of investigations, to a general study of the air which we breathe in buildings. This air we all know is, somehow or other, not as good for us, even under the best conditions of ventilation, as the open air

For example, children in open-air schools systematically show greater increases in the number of red blood corpuscles during the school term than during vacation The investigations of Benedict, Atwater, Paul, Heyman, Ercklentz and Flugge, and of Dr Leonard Hill, of the London Hospital Medical College, have given us a body of as yet undigested, although fundamentally important, information

Dr Gilman Thompson and Dr. Brennan, of New York City, have changed the death rates in pneumonia and certain other diseases by placing the beds of patients either out of doors

or next to open windows These two men think that we ought to do away with all systems of ventilation and use simply natural ventilation—open windows. On the other hand, Dr. Leonard Hill writes me as follows

I have not published in extenso my researches on ventilation and have only communicated the general drift of them to the Institution of Heating and Ventilating Engineers over here, in whose transactions my remarks appear

The whole point of my work is to force attention to the need of cool air of average humidity It is not the actual percentage of O_2 or CO_2 that matters, but the temperature, the humidity and the movement of the air in houses, schools, etc

I visited yesterday a London County council school in which is installed a Plenum system with separate shaft to each school room, giving a moving air at 67–60° Fahrenheit and about 70 per cent relative humidity All windows and doors are kept closed The result is admirable, lively, attentive children (at 4 P.M.) and masters looking fresh, no smell of human beings—this was only noticeable when one stood actually among the boys, not in the free spaces of the schoolroom The headmaster has had hardly any zymotic disease, and in every respect reports better conditions than in neighboring schools with no such efficient system The children are reported to eat more after coming to school

We know definitely that the difference between good and bad air does not consist primarily or to any great extent in variations of oxygen or carbon dioxide, and that there is no such thing as a subtle human poison (anthropotoxin) which varies in proportion to the CO_2.

We have tables which show the different temperatures and how air at, say, 32 degrees, with adequate relative humidity, becomes, when raised in temperature to, say 70 degrees, air practically without moisture It appears that one of two things must have happened—either the heat must have contracted the existing moisture or the capacity of the air for moisture has been vastly increased by the rise in temperature.

Practically all of the best manuals of the heating and ventilating engineers tell us that with a good system of ventilation the opening of windows causes only danger; yet, as a matter of fact, children in rooms so treated do not exhibit the distressing conditions referred to at the beginning of this letter

I have already secured and digested all of the literature to which reference is made in exhaustive bibliographies, indices, and the like, on the subject of air, changes in oxygen, CO_2, and so on, as well as the literature covering the relations of the vaso-motor system to the emotions on the one hand, and to skin circulation on the other

I believe that the larger part of the question as to why vitality is decreased indoors can be answered through the correlation of these facts, which I already have There are, however, certain facts which I have not, and which, so far as I have been able to find out, no one has studied I am not a physicist, and do not know—neither do I know whether the physicists know—the reason why raising the temperature of air increases its capacity for water—in fact, its thirst for water

I am writing to ask if any of the readers of SCIENCE know of any experiments which will throw any real light on the following questions

Is there any difference between steam and humidity? Does steam act strictly in accordance with the ordinary laws governing the movement of gases? Does humidity in the air act exactly as steam does? I suspect that it does not, because heat causes steam to expand, whereas, when we raise the temperature of the air its capacity for moisture becomes vastly increased, which shows either that the steam has contracted or that the air has been altered in such a way as to permit of its absorbing a larger percentage of moisture than it did before

I confess to a feeling of hesitation in presenting questions which must seem so elementary to your readers, yet when I presented to the American Society of Heating and Ventilating Engineers[1] some of the facts that we have recently discovered about the ventilation of school rooms in relation to the physical and mental condition of children they said that I

[1] *Heating and Ventilating Magazine*, February, 1911

was upsetting the very foundations upon which heating and ventilating science was built.

It seems as if there must be somewhere in existence the knowledge which we need at the present time. Man has become in a comparatively few years a preeminently house-abiding creature. He lives in localities which are paved, where there is little opportunity for evaporation, which is a necessary condition for human living. Present conditions are not right. Does any one know in what respect our present schemes of ventilation are wrong, why delicate children and tuberculous persons get well out of doors, and fail to do so in-doors, and what we need to do to make in-door living as healthy as out-door living? If we can find the answers to these questions we shall have discovered something which will affect the vitality of all the children, and ultimately of all the adults, who live in buildings throughout the civilized world.

Any reference to original sources which any of your readers can give will be most gratefully welcomed.

"MUTATIONS" OF WAAGEN AND "MUTATIONS" OF DE VRIES OR "RECTIGRADATIONS" OF OSBORN

IT is important to distinguish clearly between what may be called the "mutations" of Waagen, the "mutations" of De Vries, and the rectigradations of Osborn. By careful examination of Waagen's original paper and the usage of this paper on the continent by subsequent paleontologists it appears certain that the mutations of Waagen are stages of transition between Linnæan species occurring in direct lines of phyletic ascent. These stages are distinguished by progress, although perhaps very slight in a number of different characters. The mutations of De Vries have not been distinguished in paleontology, but only in botany, and through botany extended to zoology. They represent the sudden or discontinuous jumps or saltations through which new characters arise. Definite direction is given to these characters only through selection. The "rectigradations" of Osborn are different in significance from either of the above, the term refers to the stages of single new characters occurring at definite points, hence originally termed by Osborn "definite variations." The mutations of De Vries can not be used by paleontologists, with whom the original term *saltation* would be preferable.

HENRY FAIRFIELD OSBORN

SCIENTIFIC BOOKS

Inheritance of Characteristics in Domestic Fowl. By CHARLES B. DAVENPORT. Carnegie Institution of Washington, Publication No. 121. Pp. 1 + 100, Pl. 1–12. 1909. Issued February 7, 1910.

This quarto volume contains a detailed account of the results of the continuation of the studies on inheritance in domestic poultry carried out by Dr. Davenport at the Station for Experimental Evolution at Cold Spring Harbor, the first instalment of the results of these investigations having appeared as Carnegie Institution Publication No. 52. A great mass of new and interesting facts are brought forth in the present work. The book is divided into twelve chapters, of which the first eleven deal severally with some of the characters which experience shows to be most difficult of definite analysis in respect to their hereditary behavior. Nearly every character discussed is one which at first acquaintance appears not at all to follow Mendelian principles (at least in their simplest form) in inheritance. Because of this fact they are of all the greater interest and significance to the student of heredity, and any systematic and thorough attempt at their analysis, such as is here made, is most heartily to be welcomed and commended, even though one may not be prepared to accept *in toto* the final interpretations reached. The extensive collection of facts brought together in this work loses none of its value if the theoretical interpretation should later be changed.

Chapter I. deals with the inheritance of the split or Y comb which appears in the progeny of a cross between a single-combed bird and one possessing a V or "horned" comb, such as

is found in the Polish fowl. The essential facts brought out are that the proportion of the median element to the lateral elements of the Y comb varies in the F_1 progeny all the way from 0 to 90 per cent. of median element In the F_2 and subsequent progeny the amount of median element is distinctly correlated with the amount present in the parents The author's interpretation of this is that median comb is imperfectly dominant over no-median comb, and that the degree (or potency) of dominance is inherited Chapter II deals with the inheritance of the extra toe found in various breeds of fowls The facts here are that while "extra toe" is sometimes dominant, it sometimes fails to dominate Lumping all statistics together, it would appear to be the case that the greater the degree of dominance of extra toe in F_1 the higher the proportion of polydactylous young produced in subsequent generations, thus apparently confirming Castle's conclusions regarding the inheritance of degrees of polydactylism in guinea-pigs Analysis of the data with reference to gametic constitution of the parents, however, leads plainly to the conclusion that "the average condition of toes in the offspring of second or later generation hybrids can not be used as evidence of inheritance of the degree of parental development of the toes, since these are dependent upon the same basal cause, namely, the hidden gametic constitution of the parents"

Chapter III deals with syndactylism, or "web foot" condition This character apparently segregates as though it were dominant to normal foot, though the dominance itself may fail to appear in F_1 Chapter IV deals with rumplessness, a character of certainly puzzling behavior in inheritance Here the author's earlier provisional conclusion that rumplessness is recessive is reversed, and now this condition is held to be dominant, the allelomorphic factors being "inhibitor of tail" and its absence. The principle of imperfection of dominance is adduced to explain the fact that the F_1 progeny are tailed. Some data regarding the inheritance of presumably congenital winglessness are given in the next chapter, but definite conclusions are not reached. The next two chapters present some very valuable evidence on the much-mooted problem of the effectiveness of selection of fluctuating variations The characters dealt with are booting (feathering of legs) and nostril form. The facts here are of great importance and almost unique in the literature in that *they give for a bisexual organism data as to definite grades of the character in individuals of known gametic constitution with respect to this character* The results show at once the inherent fallacy of the basic assumption of the biometric method of dealing with inheritance, which tacitly assumes that all somatic variations are of equal hereditary significance,[1] and at the same time the failure of selection of fluctuating variations within a *gametically homogeneous* population (= the nearest thing to a "pure line" one can ever get in a bisexual organism) to produce any result. If all degrees of booting in parent and offspring of all sorts of gametic constitution are lumped together in one table there is a sensible correlation between parent and offspring. One might hence conclude that grades of booting are inherited in a blending fashion, and could be genetically modified by systematic selection of slight "favorable variations" If, however (and in showing this with such precision and clearness lies one of the most valuable contributions of the work), a table is made in which the individuals included are homogeneous gametically there is no correlation whatsoever between parent and offspring in respect to grade of booting The offspring of parents with "much boot" have on the average no more of the character than those whose parents have "little boot," provided both sets of parents are gametically alike as regards "booting." Under these circumstances one would obviously not make progress in selecting for increased booting Nostril form shows the same thing.

The next two chapters deal with crest

[1] Cf. a more detailed discussion of this point in a paper entitled "Biometric Ideas and Methods in Biology Their Significance and Limitations," which is shortly to appear in "Scientia"

(showing that this structure depends upon two gametic characters, instead of one as hitherto supposed), and with comb-lop (showing that the direction of the lop is not apparently inherited). Chapters X and XI deal with various phases of the inheritance of plumage, color and pattern. A general gametic formula for poultry coloration is worked out and evidence presented in its favor. Data are given regarding the inheritance of certain pattern types.

The last chapter is devoted to a general discussion of certain theoretical matters of prime importance. Stress is laid upon the possible significance of "inhibitors" in addition to "determiners" in ontogeny. The "principle of imperfect dominance" is discussed at length. One fancies that here is where the greatest disagreement will be found amongst students of the subject. The reviewer, frankly, is unable to see that degree of heuristic worth in this concept which the author seems to find. It seems possible to account for all the facts on which this concept rests in other ways, not any the less in accord with Mendelian principles. Virtually these facts amount to an *apparent* failure of segregation. One may safely say that practically all students of inheritance whose study involves a real, first hand acquaintance with the living, breeding organisms are deeply impressed with the precision and definiteness of segregation *generally*. When apparent exceptions to the law of precise segregation occur one's zeal is aroused to discover the cause. There is a wide range of physiological factors beyond such things as "imperfection of dominance" which must be considered here (*teste* the work of Tower and of Tennent, for example). Probably every one will admit that the data now available do not permit any final conclusion as to what are the primary factors involved in causing apparent exceptions to Mendelian principles, either in general or in particular cases. What clearly are needed are more of such extensive collections of definite experimental data as are furnished in the work under discussion. We may well observe that caution expressed by Robert Boyle as an apology for not taking a more decided stand on theoretical questions: "having met with many things for which I could assign no probable cause, and with some for which many different ones might be alleged, I dare speak positively and confidently of very few things except of matters of fact."

RAYMOND PEARL

The Teaching Botanist. A Manual of Information upon Botanical Instruction. By WILLIAM F. GANONG, Ph.D., Professor of Botany in Smith College. Second edition. Pp. 12 + 439, illustrated. New York, The Macmillan Company. 1910.

At a time when the teaching profession is being assailed on all sides with demands for a practical education, and when the meaning of "practical" is, in the main, materialistic, those teachers in botany still committed to ideals, but perhaps finding difficulty in harmonizing them with the proper demands of those seeking immediately useful training, will find a champion in the author of "The Teaching Botanist." Professor Ganong has worked long and consistently with the avowed purpose of trying to solve the problem of the content and method of an elementary course in botany. He may therefore be looked upon by the teacher seeking guidance as among the safest and surest. He would be the first to disavow the claim that he has quite answered the question to which his book is a large and satisfying reply, but we do not hesitate to say that he is far along on the right track.

"The Teaching Botanist" in its present form is called a second edition, but is very largely a rewriting. On the side of information, which the teaching botanist desires to have respecting the materials with which he deals, it has been brought down to date. The results of actual teaching experience during the last few years have been set down. In this sense the book is practical, in some directions almost encyclopedic, and will stand in good stead to one who is planning courses or equipping a laboratory. This will be understood to include also the matter of books, which are well discussed, and of which a full

list, so far as pertains to the teaching of elementary botany, is provided. Since school boards are sometimes in a hurry for data, it would have been well to facilitate the teacher's task by indicating in the list itself the relative values of the various books, so that a limited choice might be quickly made. This end is, however, largely attained in the reading of a chapter, but in a less concise way.

A very valuable addition in the present book are the suggestions given for the growing of plants in windows in pots and boxes. But few schools are able to do more than this, and any practical help in this apparently easy, but really rather difficult matter, will prove very welcome, especially as this part of the text comes from the hand of Mr. Edward J. Canning, than whom few are more skilful in horticultural practise. An additional suggestion will not be amiss, that tin cans are usually better than pots for house culture. Indeed, they are exceedingly useful for much laboratory experimentation. The jagged rims may be melted off, while a coat of asphalt paint will make them sightly.

During the past few years Professor Ganong and some of his more advanced students have systematically investigated the commoner plants with particular reference to their adaptability for demonstration and laboratory experimentation, while Professor Ganong himself has worked arduously in the perfection of apparatus of more refined type adapted to school and college use. The excellent data and apparatus thus obtained are available in *The Botanical Gazette* and in another book, "Plant Physiology," properly to be regarded as a companion volume to "The Teaching Botanist," and which should, with this, be in the hands of every ambitious teacher.

The second part is devoted to a detailed discussion of a synthetic course, the content of which is widely known through the work of the Committee on Education of the Botanical Society of America, of which Professor Ganong is the chairman. The method of presentation is left, in the report of that committee,[1] as a matter of choice to the teacher, but the book before us will do much to advance the recognition of the principle of synthesis. The account, covering 150 pages, may be regarded as a condensed log of a successful teacher, and gives the practical pedagogy on every difficult and important point. The fundamental principle, that of synthetic treatment of allied structural and physiological topics, has much to commend it, the chief of which is the overwhelming importance of physiology. The reviewer is glad that the efforts of Professor Ganong have been in this direction, since it is principally this phase of botanical science which must come to the front in the botany taught in schools of agriculture. These are rapidly multiplying, and many young teachers are going out year by year into this work who need much help along the right path.

Of most permanent importance, in the opinion of the reviewer, is the chapter on the Training and Traits of the Good Botanical Teacher. It is full of good common sense coupled with a clear vision of the ideal. The teacher who is troubled because he can not do research will find in this homily some other matters to think about and other ways of advancing his science than in striving to do the work of others whose business it is. There must be a great majority of good botanical teachers whose chief interest is the development of the teaching aspect of the science, and whose effort is legitimately expended in this way. To such Ganong brings a message.

FRANCIS ERNEST LLOYD
ALABAMA POLYTECHNIC INSTITUTE

[1] This report is printed as an appendix.

Lehrbuch der anorganischen Chemie. Von Professor Dr. H. ERDMANN, Direktor des Anorganisch-Chemischen Instituts der Königlichen Technischen Hochschule zu Berlin. Fünfte Auflage (Dreizehntes bis Sechszehntes Tausend). Mit dem Portrat des Verfassers in Gravure, 319 Abbildungen, 95 Tabellen, einer Rechentafel und Sieben Farbigen Tafeln. Braunschweig, Friedrich Vieweg und Sohn. 1910. Pp. 805. 16 Marks.

A new edition of "Erdmann" will be welcome to every chemist who has read the earlier editions This book is well known but not as well as it deserves When the first edition appeared thirteen years ago, it was recognized as the best existing one-volume text-book of descriptive chemistry, each succeeding edition is an improvement on its predecessor

The present fifth edition has a melancholy interest as the last work of the author Erdmann wrote the preface but a few days before his accidental death by drowning while sailing on a lake near Berlin. He was an active worker in several fields of chemistry, but will be best remembered for the "Lehrbuch"

What are the chief features of this book? It is written for advanced students, not for beginners It is essentially descriptive It opens with a condensed but admirably clear and complete statement of physical-chemical laws and methods contained in an introduction of 84 pages The remainder of the book treats of the elements and their compounds, and is chiefly descriptive, both chemical and physical properties being considered, technical methods and experiments profusely illustrated by excellent diagrams form a prominent feature of the book.

To give the reader an idea of the scope of the book, the headings of the paragraphs of one of the shorter and simpler chapters may be given It is worth the reader's attention The chapter on hydrogen fills 21 pages, it includes 4 tables, 22 diagrams and a beautiful colored plate of the spectra of hydrogen, oxygen and nitrogen The chapter begins with the present and the old names of the element in German and the present name in English, French, Russian and Spanish The physical constants follow; then the following paragraphs—occurrence in the universe, on the earth free and combined, relative weights of chief elements in earth's crust compared with relative number of their atoms, discovery, preparation, hydrogen as by-product; as unit of gas densities, free hydrogen has the density 2, specific gravity of hydrogen compared with air and with water—determinations of Regnault, Rayleigh, Cooke, Leduc, Morley and Thomsen; normal pressure and normal temperature, polarization, molecular speed, diffusion, effect of change in temperature and pressure on expansion, hydrogen the legal basis of thermometry, Kelvin's phenomenon, liquid hydrogen, critical pressure, chemical activity, action on water, on the halogens, on oxygen, combustible, metallic modification of hydrogen, nascent state, as unit of atomic weights, density in palladium alloy compared with densities of alkali-metals, as reducing agent, practical uses, lifting capacity of balloons, filling balloons, hydrogen as fuel, spectrum Then follows the section on experiments and technique with the diagrams In addition to the familiar apparatus and experiments may be mentioned Bucher's apparatus for quick generation of large volumes of hydrogen from aluminium and sodium hydroxide, or from calcium hydride (hydrone), Kammerlingh-Onnes's apparatus for liquefying hydrogen, the triple-walled Weinhold modification of the Dewar flask, experiments with liquid and with solid hydrogen, griessheim process for preparation of large quantities of hydrogen

Not only do we find matter in this book which is not given in other one-volume textbooks, but we find something new concerning nearly every element and important compound which was not in the last edition, for the author introduced a reference to every important discovery if it appeared in the journals before the edition went to press

The elements are treated in the main in the order of the periodic system, though Erdmann makes but little use of the system, describing it in the closing chapter His own arrangement of the elements in a spiral curve—given on a separate table—is interesting.

A singular flaw in the book is the lack of a proper treatment of the subject of steel The data given are scant, scattered and empirical. Thus vanadium steel is barely mentioned and only in the chapter on vanadium. This is, however, but a small matter compared with the general excellence of the book. Translations are not known to the reviewer The frequent appearance of new editions has probably de-

ferred translators. The cost of adequate production might deter publishers Most of those who need a book of this kind would prefer to use the original

The publishers of the book have used a thin, tough, opaque paper and a close clear type, thus bringing into one volume of readable size matter which with other paper and type would fill two volumes The diagrams and particularly the colored spectra plates are very fine The price of the book is comparatively very low

E RENOUF

Sewage By A. PRESCOTT FOLWELL Sixth Edition 8vo, pp 506, cloth New York, John Wiley & Sons $3 00

The first 358 pages of this new edition are devoted to detailed descriptions and directions for the design, construction and maintenance of sewers and their various appurtenances, as used for the removal of those wastes that are conveyed from the household by water-carriage in underground channels The book is a comprehensive one in this respect, serving not only as a useful guide to the student in sanitary engineering, but also as a valuable reference book to the practical engineer and the sanitarian

Specifications, forms of contract and procedures for putting such work under contract are given in a manner to engage the attention of the city official Cost data are analyzed with much detail and should prove of interest to engineers and contractors

Since the first edition of this book appeared eleven years ago, there have been a number of features which have arisen for discussion, and these have been judiciously embodied in the sixth edition From the strictly engineering standpoint, they relate particularly to the use made of concrete

The chapters on the ventilation and flushing of sewers are well prepared They wisely advocate the construction and operation of sewers so as to keep as fresh as possible both the sewage itself and the air within the sewers The importance of guarding against putrefaction in sewers and sewer-connections is becoming more and more appreciated, particularly by those who have to do with sewage purification It is gratifying to note that the old idea of trapping the main house drains is not favored, but preference is given to ventilating the street sewers through the house connections with pipes extending to above the roofs, as is the custom on the continent of Europe The discussion of this subject should prove of interest to sanitarians

Pages 359–492 are devoted to the subject of sewage disposal and have been practically rewritten All the principal aspects of sewage disposal by dilution and by treatment in works of artificial construction of various types are well outlined The book is not intended to be an exhaustive treatise on sewage disposal, but it is a well-balanced review of the subject which will prove serviceable to students in sanitary science, as well as to health officers, city officials or others interested in the general subject

The book has been brought well up to date, as is shown by the statements given with respect to the Emscher tanks for the clarification of sewage as recently practised in western Germany with a marked degree of success, showing much improvement over the so-called "septic tanks"

The point of view that prevails generally throughout the closing chapters of the book is a practical one Experiences with sewage disposal on a large scale are used frequently in illustrating methods and processes

Without doubt, the enlarged edition of this book should prove very useful in the classroom and in the library of those who are interested in the advancement of sanitary science. The book is well edited and indexed, and it contains 46 illustrations and 31 tables

The arrangement of the book for class-room use will doubtless appeal to teachers, as it shows the results of Professor Folwell's successful experience for some years as head of the department of civil engineering of Lafayette College, prior to his taking the editorship of the *Municipal Journal and Engineer*

GEO W FULLER

SCIENTIFIC JOURNALS AND ARTICLES

THE opening (January) number of volume 12 of the *Transactions of the American Mathematical Society* contains the following papers

L E Dickson "An invariantive investigation of irreducible binary modular forms"

W H Bates "An application of symbolic methods to the treatment of mean curvatures in hyperspace"

H F Blichfeldt "On the order of linear homogeneous groups (fourth paper)"

J L Coolidge "The metrical aspect of the line sphere transformation"

Edward Kasner "Natural systems of trajectories generating families of Lamé"

L E Dickson "A fundamental system of invariants of the general modular linear group with a solution of the form problem"

R D Carmichael "Linear difference equations and their analytic solutions"

THE February number (volume 17, number 5) of the *Bulletin of the American Mathematical Society* contains Report of the fourth regular meeting of the Southwestern Section of the society, by O D Kellogg, Report on "University courses in mathematics and the master's degree," by the American sub-committee of the International Commission on the Teaching of Mathematics, Review of Doehlemann's Geometrische Transformationen, zweiter Teil, by Virgil Snyder, Shorter Notices Sylvester's Collected Papers, Vol III, and Bachmann's Niedere Zahlentheorie, zweiter Teil, by L E. Dickson, Burali-Forti and Marcolongo's Eléments de Calcul vectoriel, by E B Wilson, Lebon's Gaston Darboux, by J W Young, Killing and Hovestadt's Handbuch des mathematischen Unterricht's, by D. D Leib, Amodeo's Analisi algebraica elementare, by C L E Moore, Rietz and Crathorne's College Algebra, by J V McKelvey; Planck's Prinzip der Erhaltung der Energie, second edition, by E B Wilson. "Notes", "New Publications"

THE March number of the *Bulletin* contains Report of the seventeenth annual meeting of the society, by F N Cole, Report of the winter meeting of the Chicago Section, by H E. Slaught; Report on "Preparation for research and the doctor's degree in mathematics," by the sub-committee of the International Commission on the Teaching of Mathematics, Shorter Notices Frankland's Theories of Parallelism, by D E Smith, Vogt's Synthetische Theorie der Cliffordschen Parallelen, by E B Cowley, Bruns's Gruppenschema fur zufallige Ereignisse, by H L. Rietz, W W. Johnson's Elementary Treatise on the Differential Calculus, by E W Ponzer, Becker and Van Orstrand's Hyperbolic Functions, Fabry's Problèmes et Exercices de Mathématiques générales, and Couturat's Internacione matematikal Lexiko en Ido, by J B Shaw, Richarz's Anfangsgrunde der Maxwellschen Theorie, by E B Wilson "Notes", "New Publications"

THE FIFTH ANNUAL REPORT OF THE PRESIDENT OF THE CARNEGIE FOUNDATION

PRESIDENT PRITCHETT'S annual report gives a full and clear statement of the business of the Carnegie Foundation for the Advancement of Teaching during the year ending November 30, 1910, and includes an essay on the relations of colleges and secondary schools

The University of California, Indiana and Purdue Universities, and Wesleyan University have been added to the accepted list of the foundation The two state universities—for Indiana and Purdue form together essentially one state university—obviously meet standards which allow the admission of colleges such as Beloit, Carleton, Coe, Dickinson, Drake, Drury and Knox The tax-supported universities previously admitted are Michigan, Wisconsin, Minnesota, Missouri and Toronto It seems to the present writer most unfortunate that the executive committee of the foundation should prescribe to the state universities what they must do in order to receive pensions Illinois has been told that it must break the agreement which it made with the professors of the medical school in Chicago, Ohio that it must reconstruct its educational policy, and the like It is to be hoped that those in control of the state universities will resent such dictation Indeed one can not altogether dismiss the suspicion that the

officers of the foundation have the same hope, in order to be released from obligations which they could not meet.

Wesleyan University has amended the charter which made it ultra-denominational—for it required not only the president and a majority of the trustees, but also a majority of the professors to be members of the methodist episcopal church—and although one fourth of the trustees are elected by the conferences of the church, it has complied with the rules of the foundation Other institutions which are altering or trying to alter their church affiliations should know that the foundation will be very cautious in assuming further financial responsibility

This appears to be at last clearly acknowledged by the president and the executive committee The president makes the acknowledgment retroactive when he writes

In every report issued by the Carnegie Foundation, the effort has been made to call the attention of colleges and universities to the fact that the endowment in the hands of its trustees would provide at most an adequate retiring allowance system for only a small minority of the institutions in the United States and Canada bearing the name college or university This was most strongly urged even in the First Annual Report.

But in his first annual report, President Pritchett estimated that with the original endowment the foundation could accept from one hundred to one hundred and twenty institutions,[1] including payment of pensions for length of service He wrote

It may therefore be safely assumed that while the income of the Foundation is sufficient to carry out the original plan of the Founder it is not sufficient to extend the system of pensions, at least at first, beyond the scope which he indicated in his letter of gift It would seem therefore clearly the true policy of the Trustees at the inauguration of the Foundation to work within these limits, giving a generous interpretation to the terms "sectarian" and "state" control

In his letter of gift, Mr Carnegie wrote· "Expert calculation shows that the revenue will be ample" "to provide retiring pensions for the teachers of Universities, Colleges and Technical Schools in our country, Canada and New Foundland"

The state of the finances of the foundation is shown in the report of the treasurer, from which it appears that the receipts for the year were $543,881 and the expenditures $538,148, leaving a surplus income less than $6,000 The obligations undertaken for the current year leave a deficit of nearly $100,000 This will doubtless be met from the income of the further five million dollars which Mr Carnegie has consented to give for tax-supported institutions He wrote to the president of the foundation on March 31, 1908 "I understand from you that if all the State Universities should apply and be admitted Five Millions more of five per cent bonds would be required" But there are eighty-three institutions supported by states and provinces, of which but eight have as yet been admitted to the accepted list of the foundation.

If such of these institutions are accepted as fulfil the educational requirements originally set by the foundation, the income next year would not meet the expenses, and thereafter the deficit will increase at a rate not less than $100,000 a year It will be necessary for Mr Carnegie to give at least two million dollars each year in order that the income may meet the increased charges

Under the circumstances it is not surprising that the executive committee has voted that it is not expedient in the future to grant retiring allowances outside of the accepted list, except in cases of especial significance in institutions whose standards are so advanced that within a short time the institution will be ready to apply for admission to the Foundation.

How incompletely even such a great gift as Mr Carnegie's establishes a pension system for higher education throughout the country is illustrated by the fact that Knox College is the only institution accepted in the state of Illinois and Tulane the only institution south of Maryland and Missouri.

The financial inability of the foundation obviously accounts for the discontinuance of

[1] More than existed, having the educational standards required by the foundation, and being non-denominational and non tax supported.

the length of service pensions What needs explanation is why they were established, why they were discontinued in the manner adopted and why they were not paid to those to whom they had been promised Suppose that Mr. Carnegie in order to get better domestic servants and at lower wages had promised that those who wished could retire after twenty-five years of service with half wages If he found that the arrangement did not work well or that he did not have enough money to keep up his establishment, he might very well have employed no new servants on these terms But would he have broken his engagement with those who had served part of the time; and, if so, what would have been the decision of the courts if suit had been brought?

In his report Dr Pritchett dismisses the breaking of the pledges of the foundation lightly with the single remark

> The experience of the year has confirmed in the judgment of the trustees the wisdom and essential justice of the action taken a year ago

Now this is a truly remarkable, indeed an almost incredible state of affairs. The present writer has discussed the matter with some two hundred university professors in the course of the past year, and so far as he remembers not a single one of them regarded the action of the trustees as other than unwise and unjust In the act of incorporation the objects of the foundation are stated to be to provide pensions of two kinds. (1) for long and meritorious service and (2) for old age, disability or other sufficient reason, and further "to do and perform all things necessary to encourage, uphold and dignify the profession of the teacher and the cause of higher education" In the method used to give up the pensions for length of service the foundation has certainly not fulfilled the obligations specified in the second part of its charter

It is obvious that unless Mr Carnegie greatly increases the endowment of the foundation it can not meet its present obligations. They obtain most of all in the case of the younger men now entering the academic career in view of its promises It will doubtless be necessary to give up the retiring allowances, for age and confine them to disability The present writer does not regret this, for reasons which he has fully stated (SCIENCE, April 2, 1909)

Retirement at the age of sixty-five has substantially the same drawbacks as retirement after twenty-five years of service Men who are less competent or who are not in favor with the administration will be retired, and instead of security and loyalty, there will be unrest and bitterness The president will be quick to retire professors because their pensions are not paid by his institution, but from an outside source There is no more reason for retiring professors at sixty-five than justices of the supreme court There should be pensions (or still better full salaries after long terms of service) for disability, but these should be paid by the university It would have been far better if the Carnegie Foundation had given its income as an endowment to one institution after another for the establishment of a pension system Its present financial difficulties would have been avoided, and the dangers of a centralized autocracy would have been escaped

It is to be hoped that when the trustees of the foundation abandon the retiring allowances at the age of sixty-five years, they will do so in a manner that will "encourage, uphold and dignify the profession of the teacher and the cause of higher education"

THE TYPE OF COLUMBINA SPIX

A FEW years ago I discussed the question of *Columbina vs Chæmepelia* in *The Auk*,[1] contending that the designation of *Columba passerina* Linn by Gray in 1840 as the type of *Columbina* was valid, and that his later designation of the same species as the type of *Chæmepelia* rendered *Chæmepelia* (Swainson, 1827) a synonym of *Columbina* (Spix, 1825) The genus *Columbina* originally contained four species, all described as new, one of

[1] Vol XXV, 1908, pp 301–306

which (*griseola*) proves to be only a slightly differentiated subspecies of *C passerina* For many years, or until the custom came in of recognizing subspecies, the real status of *griseola* was that of a synonym of *passerina*, which up to a recent date[6] had a commonly recognized range extending from the warmer parts of the United States south through the West Indies, Central America and South America to Paraguay and Peru, thus including the type locality of *griseola* When the original *passerina* came to be divided into numerous subspecies, *griseola*, as recognized by recent leading authorities, became *Chæmepelia passerina griseola*

In my paper cited above I stated that I could "see no reason why *Columbina griseola* = *Columbina passerina griseola* (Spix) may not be properly taken as the type of *Columbina*, in accordance with rule *d* of Art 30 of the International Code respecting the equal availability of species and subspecies as types." I find it is now questioned whether this statement, owing to its form, can be taken as really designating a type for *Columbina*, and take this opportunity of stating that this was its intention To leave no doubt, I may here add *Columbina* Spix, 1825, type *C griseola* Spix = *Columbina passerina griseola* Spix

But there are other complications hovering about the type of *Columbina*, and about the propriety of the above designation, on the ground that the question is one partly of zoology and partly of nomenclature In other words, that *griseola* may not be a subspecies of *passerina* but possibly a distinct species, or a subspecies of some other species This question could not well have arisen except for a mistake made by Bonaparte, in 1854, and followed by nearly all authors for the next half century He recognized and described a species under the name "*griseola* Spix" which was not only *not* the *griseola* of Spix but bears to it no very close relationship, it being in reality the *Columba minuta* of Linnæus To this extent, and no further, is the type of *Columbina* a question of zoology, for the type of *griseola* Spix is still extant and proves to be a young female of the *passerina* group, or of "*passerina*" as formerly recognized[6]

ANOTHER SEX-LIMITED CHARACTER IN FOWLS

IN view of the number of sex-limited characters recently recorded, the report of another one may be of interest even though the experiment has not yet gone beyond the first generation

The Brown Leghorn fowl has nearly the same color as the wild *Gallus bankiva* It is a sexually dimorphic breed, with black and reddish or yellowish-bay the chief colors in the male, and with the female lighter in color and showing a characteristic black and yellowish-brown pepper-and-salt pattern on the back and wings The Columbian Wyandotte has both sexes white, with black in the neck, wings and tail

When these two breeds were crossed there were three different classes of birds in the F_1 generation There were brown females resembling the Brown Leghorn females, and gray males and females resembling the Columbian Wyandottes but having considerable black mixed with the white ground color, thus giving a grayish effect These came in the following way·

Brown Leghorn ♂ + Columbian Wyandotte ♀
= 10 gray ♂ and 8 brown ♀
Columbian Wyandotte ♂ + Brown Leghorn ♀
= 9 gray ♂ and 3 gray ♀

It will be seen that these results agree with Goodale's experiment,[1] since the gray males show considerable red or brown on their backs, as was the case with the corresponding birds in his cross between White Rocks and Brown Leghorns.

The gray females, however, unlike his barred F_1 females, also show a little brown, though this is not conspicuous They also show some

[1] *Proc Soc Exp Biol. and Med*, Vol 7, No 5, May 18, 1910

of the Brown Leghorn pepper-and-salt pattern The F_1 brown females are yellower on the fore part of the back and wings than are the Brown Leghorns They seem to resemble some of Goodale's F_1 brown females, but none are as dark as some of his Perhaps such would have appeared if a larger number had been raised

These results show that the gray pattern behaves as the barred and brown ones have already been shown to do The results may be explained as the others are Represent the gray factor by G, the brown by B, and femaleness by F Assume that both G and B are spurious allelomorphs to F[3]

The representation will be

Brown Leghorn ♂—gBf gBf
Columbian Wyandotte ♀—Gf gF
produce { gBf Gf — gray ♂ ; gBf gF — brown ♀ }

Columbian Wyandotte ♂—Gf Gf
Brown Leghorn ♀—gBf gbF
produce { Gf gBf — gray ♂ ; Gf gbF — gray ♀ }

Nothing has yet appeared to show the composition of the Columbian Wyandotte with regard to B

Several years ago a Columbian Wyandotte male was mated to a female of the Silver Laced Wyandotte breed, which has black wherever the Columbian has it and also has the feathers of the back, breast and shoulders white, edged or laced with black The F_1 birds were nearly typical Columbians, one of the males being near enough to that color to win a prize as a Columbian at a poultry show Some of the females, however, showed black edging on the tips of some of the feathers of the back One of these was mated to a Columbian Wyandotte male, and the result was practically the same as in the F_1 generation. Unfortunately, this cross was not made in the right direction to bring out the sex-limited character, but the result agrees well with that described above

A H. Sturtevant

Columbia University,
January 2, 1911

[3] Goodale's work (mentioned above) has shown that B is sex limited

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE FORTY-THIRD GENERAL MEETING OF THE AMERICAN CHEMICAL SOCIETY AND SECTION C

The forty third general meeting of the American Chemical Society and Section C of the American Association for the Advancement of Science was held at Minneapolis in the Chemistry Building at the University of Minnesota, December 28–31, 1910 The first general meeting was called on Wednesday morning

About 300 members and guests registered for the meeting Approximately 275 of these were members of the society The meeting was a thoroughly good one from the consideration of attendance, number and quality of papers, and the generally good time which every one enjoyed because of the generous hospitality of our hosts

The council of the society met on Wednesday afternoon and Thursday evening, when the general business and election of officers were considered

Wednesday evening the Minneapolis Section of the society extended a complimentary smoker to the visitors at the Commercial Club Complimentary luncheons were also prepared for the visitors during each day of the session

On Thursday and Friday afternoons excursions were made to the Minneapolis flour mills, International Stock Food Factory, St Anthony Falls Power Company, the linseed oil and paint companies On Saturday afternoon the visitors enjoyed a free excursion to the many points of interest about Minneapolis and St Paul

The following papers and addresses were given before the general meetings

"A Universal Law," President W D Bancroft

"Report for the International Committee on Atomic Weights," F W Clarke

"The Lost Arts of Chemistry," W. D Richardson

"The Basis of Industrial Efficiency," Arthur D Little

"Synthetic Metals from Non-metallic Elements," Herbert N McCoy

"Progress in Food Chemistry," H E Barnard

"Mechanism of Cell Activity," Carl L Alsberg

"Waste Wood and some of its By products," Geo B Frankforter

"The Formation of Carbohydrates in the Vegetable Kingdom," Wm McPherson

"The Efficiency of the College Graduate in the Chemical Industry," Chas F Burgess

BIOLOGICAL SECTION

Carl L Alsberg, *chairman*

I K Phelps, *secretary*

The Lecithin Content of Milk under Pathologic Conditions L W FETZER

The results show that milk obtained from animals suffering from mastitis contains less lecithin than the milk obtained from healthy animals It was further noted that where a diminution in the lecithin content took place there was a corresponding decrease in the fat content

The Antitoxic Action of Certain Nutrient and Non nutrient Mineral Bases with Respect to Plants M M MCCOOL

Extensive data were presented with reference to antagonistic action of different bases with respect to plants In the experiments reported the Canada field pea has been made the indicator, and a complete comparative study has been made of the growth of tops and roots in solutions of the different bases as follows (1) solutions containing single bases in concentrations varying from those which are non toxic to those which practically prohibit growth, (2) solutions containing two bases at concentrations including those toxic when employed alone

It was found that mutual antagonism occurs in the following combinations

Ca *vs* Ba	Ca *vs* NH_4
Ca *vs* Fe	Ca *vs* Sr
Ca *vs* K	K *vs* Sr
Ca *vs* Mg	Na *vs* K
Ca *vs* Mn	Na *vs* Mn
Ca *vs* Na	Na *vs* Sr

To express the above in terms of single antagonism, it is obvious that the second term in each of these systems could be placed first, but the arrangement given indicates that the base first given is the most important term in the combination with respect to antagonistic action

The toxicity of the various bases in distilled water, full nutrient solutions, and soil cultures have been determined likewise as additional controls upon the preceding results The tests of all of these bases in dilute nutrient solutions of any type, or in soil or sand cultures, diminishes or prevents the injurious action of the concentrations toxic in water

The Oxidative and Catalytic Powers of Soils and Subsoils M X SULLIVAN and F R REED

Surface soils have the power to oxidize easily oxidizable substances such as aloin, guaiac, pyrogallol, hydroquinone, etc When ten grams of soil are shaken with 50 c c of a 0 1 per cent. water solution of aloin, the yellow color of the aloin is changed to cherry red. On allowing the soil to settle, the solution can be filtered and the depth of color determined in the colorimeter Broadly speaking, the oxidative power of the soil is symptomatic of a good soil condition, since soils of good productivity have in general good oxidizing power, while soils of poor productivity have, as a rule, poor oxidizing power. Subsoils have little, if any, action on aloin, though occasionally the oxidizing power of the subsoil may be as great or greater than the corresponding surface soil The catalytic power of the soil or its capacity for decomposing hydrogen peroxide with the liberation of free oxygen is roughly parallel to the oxidative power in that soils known to be of good productivity have strong catalytic power, while poor soils have weak catalytic power As compared with surface soils, the subsoils have, for the most part, a weak catalytic power. The oxidative and catalytic powers of the soil are analogous to these powers in plants and animals and are modified in much the same way

Enzymotic Activities in Soils OSWALD SCHREINER and M X SULLIVAN

Within the bodies of microorganisms in plant roots and plant débris, in worms and animalcules, enzymes of various kinds must exist. Evidence of various enzymotic activities, proteolytic, amylolytic, inverting, cytolytic, lipolytic, etc, may be seen in many soils Starches, sugars, cellulose, fat and protein are speedily changed or disappear, and in many cases, especially of proteins, some of the products of digestion may be found in the soil The oxidizing and catalytic activities of the soil, comparable to the same activities in plants and animals where it has been attributed to enzymes, is especially noticeable and easy of demonstration As yet no satisfactory means have been obtained of extracting enzymes from soil to any great extent, though in soils recently cropped there is some slight evidence of the presence of enzyme like substances in the glycerine extract of the soil

Soil Organic Matter as Material for Biochemical Investigation · OSWALD SCHREINER and EDMUND C SHOREY

Attention is called to the complexity of the organic matter of soils and the fruitful field of research that it offers for biochemical investiga-

tion. The importance of the chemical character of the organic matter of the soil is considered under four heads: its effect on crops, its effect on the bacteria and fungi of the soil, its influence on the physical properties of the soil, and its relation chemically to the mineral ingredients of the soil. By the application of the biochemical methods there have been isolated in this research twenty definite organic compounds thus far from that portion of soil organic matter included in the term humus. A chart showing the classification of these compounds, as well as methods of separation, was shown. The compounds comprised paraffin hydrocarbons, acids, alcohols, esters, carbohydrates, hexone bases, pyrimidine derivatives and purine bases.

The Isolation of Creatinine from Soils: EDMUND C. SHOREY.

Creatinine has been isolated from several soils by the following method: An extract made by shaking the soil for half an hour with 2 per cent. sodium hydroxide was neutralized with acetic acid and filtered. To the filtrate a small quantity of dextrose was added, heated to boiling, and Fehling's solution added until the precipitate formed was red in color. The precipitate after washing was decomposed with hydrogen sulphide and the filtrate from the copper sulphide concentrated under reduced pressure. Creatinine, if present in the soil, is in this filtrate together with purine bases and can be separated as creatinine zinc chloride and creatinine prepared from this by treatment with lead hydroxide. The creatinine was identified by the characteristic crystalline appearance of the zinc chloride compound and by the Jaffe, Weyl and Salkouski color reactions.

The Toxic Action of Organic Compounds as Modified by Fertilizer Salts: OSWALD SCHREINER and J. J. SKINNER.

The action of fertilizer salts in restraining the harmful influence of certain organic compounds was studied, as well as the effect of the compounds on absorption. The culture solutions comprised all possible ratios of the three principal fertilizer elements: phosphate, nitrate and potassium, varying in 10 per cent. stages.

The various fertilizer salts acted differently in overcoming the respective harmful effects of the toxic compounds. The mainly phosphatic fertilizers were the most efficient in overcoming the cumarin effects, the mainly nitrogenous fertilizers in overcoming the vanillin effects, the mainly potassic in overcoming the quinone effects.

The cumarin depressed potash and nitrate removal from nutrient solution more than phosphate, the quinone, on the other hand, depressed phosphate and nitrate more than potash, the effect of vanillin was not determined in this regard. It is interesting to mention that dihydroxystearic acid, which, as previously reported, appears to act much as vanillin did, depressed phosphate and potash more than nitrate. In this respect again the influence of the various harmful substances was different.

The conclusion is drawn that different toxic substances produce definite effects in their action on plants and that the effects are modified differently by the different fertilizer salts.

On the Catalase Content of Tissues and Organs after Prolonged Fasting: P. B. HAWK, Laboratory of Physiological Chemistry, University of Illinois.

The study embraced the examination of the tissues and organs of four dogs which were subjected to periods of fasting ranging from 7 to 104 days. A pup one month old was subjected to a 7 day fast, a dog from one to two years old served as the subject of the 30 day fast, whereas the longer fasts were carried out upon mature animals. The dogs were fed a constant water ration, the water being introduced by means of a stomach tube.

At the termination of the fasting periods chloroform water extracts of the tissues and organs were prepared and their catalase values determined. The tissues and organs of normally nourished dogs were subjected to a similar examination in order to secure data for comparative purposes.

The catalase values of the fasting tissues and organs are much lower, in every instance, than those of the normal tissues and organs. It was also observed that the order of the tissues when arranged according to their catalase content is distinctly altered in the fasting animals from the order in force under normal conditions. There is apparently no uniformity as to the specific alterations which take place in the catalase content of animal tissues and organs under the influence of fasting. The data obtained from the four fasting animals under consideration are in every case different from normal catalase values, but at the same time these catalase values obtained from fasting animals exhibit marked variations when we make a comparison of the data from the four animals under investigation. It is of particular

Catalase Values

Dog	Tissue								Days
	Liver	Kidney	Spleen	Lung	Heart	Muscle	Brain	Pancreas	
Normal	67 1	66 4	8 8	7 2	4 3	2 7	0 8	0 7	
Fasting	52 7	50 4	5 1	10 8	2 6	0 0	8 2	0 5	104
Fasting	23 8	4 4	0 0	8 2	0 0	0 0	0 0	0 0	48
Fasting	34 8	46 5	0 0	0 5	0 0	0 0	0 0	0 0	30
Fasting	57 0	11 1		1 2	12 3	0 0	0 0	0,0	7
	Relative Order of Tissue								
Normal	Liver	Kidney	Spleen	Lung	Heart	Muscle	Brain	Pancreas	
Fasting	Liver	Kidney	Lung	Brain	Spleen	Heart	Pancreas		104
Fasting	Liver	Lung	Kidney						48
Fasting	Kidney	Liver	Lung						30
Fasting	Liver	Heart	Kidney	Lung					7

interest that the tissues and organs of the dog which was subjected to the most prolonged period of fasting exhibit less alteration from the normal than do the tissues and organs of those animals which were subjected to much shorter fasts

Demethylation in the Body WILLIAM SALANT and I K PHELPS

Determinations of the urinary purins precipitable by copper sulphate in sodium bisulphide after the administration of caffein indicate that individuals of the same species vary considerably in their power to demethylate this substance The amounts of purin nitrogen obtained from the urine of two dogs when a total of four hundred milligrams caffeine per kilo were given in eight days were eight and thirty two milligrams purin nitrogen per kg After feeding three hundred milligrams caffeine per kilo to these animals during the next four days eight and twenty-two milligrams purin nitrogen per kilo were obtained After an interval of eight days the administration of caffeine was resumed and much greater amounts of purin were found in the urine In one case the amount of purin per kilo was increased two hundred per cent, although the amount of caffeine given was only twenty per cent greater In the other dog the increase of purin nitrogen was sixty per cent greater, the amount of caffeine in this case was likewise increased by twenty per cent It was further observed that demethylation remained relatively unchanged when the caffeine was given daily

Some Experiments on the Influence of the Digestive Process on the Excretion of Carbon Dioxide G O HIGLEY

The apparatus used in this work was the balance-chemograph

The food employed was one half a pound of broiled beef steak at each meal The four subjects were students in the University of Michigan No food was taken by the subject during the five hours preceding an experiment The subject reclined for fifteen minutes, then the "normal" was determined The food was now eaten and fifteen minutes thereafter, and at regular intervals, determinations of the carbon dioxide excretion were made

The maximum increase over the normal was twenty five per cent in one case and only 7 7 per cent in another case

The promptness of the increase was also quite different, the increase over the normal being at the end of thirty minutes, 1 2 per cent, 7 per cent and 11 9 per cent, respectively, in the case of three subjects

The Incompatibility of Alcohol with other Nutrients J E SIEBEL, JR, MD

The incompatibility as subject of this paper refers to a certain incompatibility with nutrients, especially in persons constitutionally affected, which is due to the fact that the human system, having a choice, disposes first of alcohol before other nutrients are affected in metabolism, as proved by the classic feeding experiments of Atwater and confirmed by the author's researches on the electromotive force of nutrients showing a maximum result for alcohol

Accordingly and supported by professional experience, it is concluded that for people constitutionally afflicted with disorders in which, as in arthritis and glycosuria, excesses of proteids and saccharine food are to be avoided, such excesses

are especially harmful in connection with the use of alcoholic beverages, unless special rules of nutrition, given by the author, are followed

Improvements in the Exact Determination of Nitrogen in Feces ISAAC KING PHELPS

The difficulties of an exact aliquot and of loss of nitrogen in drying the viscous material are met by each of two procedures

The first procedure consists in dehydrating the moist mass by treatment with acidified alcohol and ether and filtration The dry residue is then sifted and the nitrogen determined in the residual material, consisting of undigested material, in the powder obtained by sifting (which represents the residue from food) and in the alcohol ether extract

The second procedure consists in partially decomposing the moist material with concentrated sulphuric acid by heating in a steam bath until a *homogeneous mass is produced* This is then aliquoted and the nitrogen determined in the aliquot

The test of accuracy and adaptability of these procedures shows that they are both excellent

The Excretion of Chlorides under the Influence of Copious Water drinking between Meals S A RULON, JR, and P B HAWK

Three experiments were made on the influence of copious water drinking between meals upon the excretion of chlorides The subjects were young men ranging in age from 22 to 29 years Each experiment was divided into three periods, a *preliminary* period during which nitrogen equilibrium was attained through the feeding of a uniform ration of low water content, a *water* period during which the uniform ration was supplemented by the drinking of large volumes of water *between meals*, and a *final* period in which the conditions of the preliminary period were in force

In two of the experiments there was a pronounced increase in the output of chlorides upon the days of added water intake, with a return to normal during the final period This augmented excretion of chlorides is interpreted as indicating that the large volume of water ingested during this period has markedly stimulated the secretion of gastric juice The excess hydrochloric acid thus passed into the intestine has been reabsorbed and appears in the urine as ammonium chloride The main bulk of the increase in the chloride excretion we believe to have originated in this way

In one experiment there was a small increase in the chloride output upon each of the days of increased water ingestion, followed by a pronounced rise in the output upon the first day following the water period Neither the flushing properties of the water nor its stimulatory efficiency as regards protein catabolism or gastric secretion offers a satisfactory explanation for the high chloride concentration observed upon the day following the period of copious water drinking

If we attempt to account for the increased output of chlorides noted during the period of copious water ingestion upon the theory that this increase originated through a stimulated catabolism of protein matter within the organism, we find it possible to account for only two per cent or less of the chloride increase on this basis

In every instance in which a portion of the urine of each day of the water period was collected in four sub periods three and one half hours in length it was observed that the maximum chloride output and urine volume occurred during the second period of the day, *i e*, from 11 30 A M to 3 P M It was also observed that the highest percentage of ingested fluid (84 per cent) was excreted during the periods of copious water intake

Resorption of Fat P F TROWBRIDGE, University of Missouri

A group of seven calves six months old were selected as being of same breed and uniform in size and condition They were fed several months until all were judged to be well fattened and all in about the same condition The one thought to be the least fat was slaughtered and analyzed as a check animal Two of the remaining were held at maintenance of body weight, two were fed so as to lose one half pound per day, and the other two were fed to gain one half pound per day. All were given the same feed, varying only in quantity One of each group was slaughtered and analyzed at the end of six months, the other submaintenance animal at the end of eleven months and the other maintenance animal at the end of twelve months The supermaintenance animal was not slaughtered, as the one half pound per day gain at his age—two years—was sufficient to make him improve in condition

All the maintenance and submaintenance animals lost in fat The long-maintenance animal gained in total protein and also in flesh protein All the animals gained in weight of skeleton from 9 5 per cent. to 16 6 per cent The skeleton of all animals gained in protein, moisture and

ash, and in fat except in that of the long submaintenance animal, which lost over 75 per cent of its original fat The animal on long submaintenance (eleven months) became greatly emaciated and the analysis showed that he had used up nearly all of his reserve store of fat, not only from his flesh, but from his skeleton The short submaintenance animal (six months) and the long maintenance animal (twelve months) had used up nearly all the reserve fat of the tissues, but had not drawn upon the supply in the skeleton

The loss in moisture is not sufficient to correspond to the loss in protein for a lean meat or connective tissue, which supports the view that in certain stages, at least, of fat resorption the fat is in whole or in part replaced by water

The normal skeleton contains about 36 per cent moisture In the long submaintenance animal it has risen to 53 per cent, while the fat content of the skeleton has dropped from 16 per cent to 3 per cent In this time the skeleton has gained nearly one per cent. of its total weight in dry protein The long submaintenance animal lost 10,627 grams in dry protein, but only 24,868 grams in moisture, which lacks about 16 000 grams of being enough to make up the protein loss to lean flesh and connective tissue. During this time the loss in fat was 43,829 grams, or about 90 per cent of the total fat present at the beginning

The Preparation and Properties of an Oxidase occurring in Fruits FIRMAN THOMPSON and HARRY P BASSETT

An oxidase was prepared from the juice of pears and was found to have a marked action in the production of a tannin like substance from gallic acid The extent and rate of this action were measured by the precipitation of the nitrogen in a solution of egg white By this means a very extensive and rapid action of the enzyme was shown Tannin determinations made by one of the standard methods also confirmed these results It was further shown by means of plate cultures that the body thus produced exhibited marked germicidal properties

A gradual decrease of soluble nitrogen in the juices prepared from various fruits indicates that a similar action takes place there on exposure to oxygen of the air The writers consider it doubtful if tannin exists as such in the normal growing fruit, believing it to be rapidly formed on injury or removal from the tree, its function being to inhibit fungous or bacterial growths

Dissolved Oxygen as an Index of Pollution GEO A SOPER and PAYNE B PARSONS

The determination of dissolved oxygen as an index of sewage pollution has been found to be reliable in the work of the Metropolitan Sewerage Commission of New York, where the quantities of sewage and conditions attending the discharge of sewage were determined and other factors in the problem known

Opinions differ as to the permissible limit of exhaustion of oxygen by sewage Some authorities consider that more than 30 per cent should not be taken from the water Others have expressed the opinion that 70 per cent was a permissible draft To the present authors it appears that no arbitrary standard can safely be established A careful consideration of the local conditions should determine the safe limit for any case

Preliminary Report on the Loss of Lime in some Drainage Waters A W BLAIR and S E COLLISON

The paper describes soil investigations involving the use of fertilizers in citrus culture in progress at the Florida Agricultural Experiment Station A description of the large galvanized iron soil tanks in use is given and rainfall records and amount of drainage water collected from the tanks for a period of three months are reported

The lime content of seven samplings of water for the three months is given in parts per million of water, and as pounds of calcium carbonate per acre

Some Poisons in Foods H E BARNARD

A general discussion of the various poisons found in foods as preservatives and as they occur in nature

Determination of Dissolved Oxygen in Water GEO A SOPER and PAYNE B PARSONS

This paper reports an accurate and rapid field method for determining dissolved oxygen in water The oxygen is determined immediately after the sample is taken

The Determination of Arsenic in Insecticides E B HOLLAND

The cooperation of the laboratory with the entomologist in a study of arsenical insecticides necessitated a great many determinations of arsenic This led to a review of the literature on the subject, careful consideration of the various methods offered, and some improvements in the iodine titration method as applied to the analyses of arsenites and arsenates.

Purification of Insoluble Fatty Acids E B HOLLAND

Finding it impossible to purchase insoluble fatty acids of a satisfactory quality, it became necessary to undertake a study of various methods for their purification

The methods that seemed the best adapted for the purpose were (*a*) distillation of the fatty acids in vacuo, (*b*) crystallization from alcohol and (*c*) distillation of the ethyl esters in vacuo, and all were given extended trial

It was found that while saturated fatty acids may be purified by distillation of either the acids or their ethyl esters, the latter method is less hazardous and much easier to manipulate, although more steps are required Crystallization

is a finishing rather than an initial process of purification

Excrement of Guayule fed Animals CHAS P FOX

During time of drought goats feed upon the tender branches of the guayule, *Parthenium argentatum* The leaves of this plant do not contain rubber, but there is a small amount present in the twigs The solid excrement of the guayule-foraging animals does not contain a trace of caoutchouc

Pingue (Colorado rubber weed) is regarded by stockmen as poisonous to sheep In this case death is caused by clogging of the digestive organs with undigested rubber Goats are not affected by guayule

Dissolved Oxygen in New York Harbor GEO A SOPER and PAYNE B PARSONS

The results of an investigation of the sanitary condition of New York harbor with respect to the dissolved oxygen is reported The analyses were made immediately after the samples were taken

The results show that there was not much difference between the amount of oxygen in the water at the surface and at the bottom except that in badly polluted sections the surface samples usually contained rather less oxygen than did the deeper ones This was contrary to expectation and is probably accounted for on the ground that the water was more impure at the top than at the bottom, a supposition supported by the fact that bacteria were most numerous at the top and by the further fact that there was more sea water near the bottom than near the top In comparatively unpolluted sections the deep samples usually contained less oxygen than the surface samples

When the comparatively pure sea water from the lower bay or Long Island Sound entered a polluted section, the amount of oxygen in the water of that section increased by the dilution

Composition of the Ash of Pickles L H S BAILEY.

On account of the use of alum in the hardening of pickles the composition of the ashes of normal pickles as they appear upon the market, and also of pickles in which alum has been used, is of importance For comparison the analyses also of green cucumbers as grown in different localities has been made. A discussion of the importance of the different constituents in the ash and the significance of the presence of these substances follows.

DIVISION OF PHYSICAL AND INORGANIC CHEMISTRY

E C Franklin, *chairman*

S L Bigelow, *secretary*

Apparatus for Measuring Vapor Pressure I H DERBY, F C GUTSCHE and F DANIELS

Two thrice tubulated glass bulbs connected together by a short glass tube are filled with glass pearls and one third filled with liquid The bulbs may be rotated horizontally on the tubes, delivering dry air and conducting away saturated air, respectively, as an axis To each end of this axis a short rubber tube is connected and a short section of glass tubing is placed in each of the free ends of the rubber tubes The rubber tubes are bent down and the short glass tubes fitted loosely over vertical tubes about which they may rotate as axes Mercury contained in a cup surrounding the junction makes a gas tight joint which yet allows rotation of the wider tubes with the bulbs

Important features of the apparatus are (1) simplicity of construction and operation, (2) rapid and complete saturation, (3) saturation at barometric pressure, (4) adaptability to the determination of vapor pressures of solutions and vapor compositions, for which purposes it was primarily designed

The Nature of Mass J E MILLS

The usual idea of mass is made clear It is shown that the modern definition of mass as expressed in the equation, $\frac{1}{2}mv^2 = mas$, is not independent of, but is dependent upon, the attraction of gravitation The attractive forces are compared, and it is shown that there is considerable reason for thinking that mass is a "gravitational charge" Facts bearing upon this suggestion are discussed

Recrystallization of Barium Sulphate H C COOPER and T S FULLER, Syracuse University

By recrystallizing precipitated barium sulphate from molten sodium sulphate at 1150° and dissolving out the sodium sulphate with water they obtained crystals of barium sulphate as long as 5 mm and as wide as 1 mm These crystals correspond to barite, the natural crystallized barium sulphate Equally good crystals of barium sulphate were obtained by recrystallization from molten barium chloride

The Tendency of Chemical Energy Conversion J E SIEBEL, Zymotechnic Institute, Chicago

In connection with the phase and mass law and Chatelier's theorem, the principle of the maximal work as a measure for affinity governs the tendency of chemical energy conversions

The maximal work which is obtainable from a chemical reaction in a reversible cycle is calculable by the second law of thermodynamics, but this law, it is explained, can be more generally expressed by substituting the intensity factor by an equivalent energy factor, in which latter form, as was shown in a former paper, it is more applicable for energy conversion with saturated vapor than the former. It is now shown that the new version is also well adapted to chemical energy conversions, and that it furnishes very simple arithmetic expressions for the solutions of the problems involved.

Nucleation of Mixed Vapors in Dust-free Air: I. H. DERBY.

The expansion ratios necessary to produce, in dust-free air, the formation of rain and fog respectively, in mixed vapors of alcohol and water and mixed vapors of methyl alcohol and water have been determined for each pair of substances at varying concentrations. The series of ratios for each pair of substances show a minimum value for certain mixtures.

A tentative explanation of this behavior rests on the assumption that the molecules of one substance act as nucleation centers for the vapors of the other, due to the fact that the vapors of alcohols are charged with electricity opposite in kind to that found in water vapor.

The Rapid Determination of Silver and Cadmium by Means of the Gauze Cathode and Stationary Anode: R. C. BENNER and W. H. ROSS.

The study of the efficiency of the gauze electrode with a stationary anode as a rapid means for the deposition of the metals was extended to include silver and cadmium. Satisfactory results were obtained for each metal by using an electrolyte consisting of potassium cyanide in a potassium hydroxide solution. White adherent deposits were uniformly obtained in this manner. Good results, however, were not obtained when using any of the electrolytes commonly recommended for the older electrolytic methods.

The Rapid Deposition of Cobalt and Nickel by Means of the Gauze Cathode and Stationary Anode: R. C. BENNER and W. H. ROSS.

A study was made of the efficiency of the gauze electrode as a rapid means of depositing the metals nickel and cobalt with currents of from three to four amperes. Excellent results were obtained for each metal with the following electrolytes which were used in the older electrolytic methods—ammonium sulphate, ammonium acetate and ammonium formate, all in ammoniacal solution. In a neutral or slightly acid solution there is a tendency to anodic deposition. The results obtained with ammonium oxalate were not quite as satisfactory as with the other electrolytes named. A number of determinations were made in solutions of ammonium carbonate. This formed a most satisfactory electrolyte, either with or without the addition of ammonium hydroxide, from which to deposit these metals.

The rate at which these elements are precipitated on the gauze electrode is practically the same for all electrolytes mentioned, and, although not quite equal to the rate at which they can be precipitated when the electrolyte is agitated by mechanical means, is rapid enough for practical purposes. This method is likewise much more satisfactory because of the simplicity of the apparatus and from the fact that, if desired, the older methods with small currents may be used with the same electrodes.

The Function of the Walls in Capillary Phenomena: S. L. BIGELOW and F. W. HUNTER.

Experimental method and results were given demonstrating that the capillary ascension of water is measurably different in tubes of Zn, Cu, Ni, Al, Ag, Pt, glass, celluloid, beeswax and paraffin. From this fact the conclusion was drawn that, in all cases except where the maximum ascension is obtained, the ascension is a measure of the adhesion between the liquid and the walls rather than a measure of the cohesion (surface tension) of the liquid.

The capillary ascensions of saturated solutions of copper sulphate, gypsum, sodium chloride, potassium dichromate and alum were measured in tubes of platinum, of glass and of the solid solute. A regularity was discovered which may be stated as follows: The adhesion between a salt and its saturated solution is nearly the same for a number of salts irrespective of their chemical nature. The paper will appear in the *Journal of Physical Chemistry*.

The Hydrocarbons in Lignite: G. B. FRANKFORTER and A. P. PETERSON.

In this paper the hydrocarbons have been studied with the idea of isolating some of the heavier ones. The first work consisted in the proximate analyses of the lignites from the various localities, ranging from the southern to the extreme northern limits of the Dakota, Saskatchewan, Alberta and Alaska lignite belts.

An average of the distillation products in these different samples was about 50 per cent. carbon

residue, 1 to 5 per cent of tar, 25–35 of condensed water The gaseous products ranged from 15 to 25 liters per 100 grams of coal The gaseous products were characterized by the very large amount of carbon dioxide they contained It varied from 20 to 40 per cent, depending upon the locality of the lignite There was an increase of hydrocarbons and a decrease of carbon dioxide in the gases from the lignites passing from south to north The samples likewise resembled bituminous coal more closely from south to north

Snow as a Means of Studying the Smoke Nuisance Geo B Frankforter

In this paper snow has been used as a means of determining these constituents After the snow had covered the ground for a given time, the amount on a square foot of ground was collected, melted and the solid matter filtered off and weighed The solids were analyzed and finally the water was examined for the soluble solids and gases

The amount of solid matter which fell during six weeks of winter weather in the cities of Minneapolis and St Paul varied from 3 to 2 69 grams per square foot within the city limits An average of ten analyses gave 1 43 grams per square foot Calculated on the basis of one gram per square foot, there would be 43 56 kilograms per acre or 27 8 tons per square mile

An average of ten analyses gave 57 16 per cent. of carbon and 42 84 per cent of ash

Average of ten analyses of the ash gave the following

SiO_2	50 50
Ca	1 13
Mg	0 31
Fe	12 10
Al	14 26
Alkalies	1 70

The snow water was then analyzed and found to contain a considerable amount of soluble matter

An average of ten analyses gave the following

	Parts per Million
Total solids	39 5
Chlorine	5 1
Free ammonia	0 26
Nitrites	0 038
Organic matter (oxygen consumed)	2 49
SO_4	4 84

A New Indicator. Chas P Fox

The bark of a Congo rubber producing vine, said to be one of the *Landolphias*, gives an aqueous extract which exhibits the properties of an indicator. Alkalies give a deep red (magenta), acids, a light yellow to colorless Change is sharp enough for use in technical work. The aqueous preparation is unstable The coloring substance is precipitated by acids

A Quantitative Expression of the Periodic Classification of the Elements. Frederick G Jackson

A chart was shown on which the atomic weights of the elements were plotted, the members of each small period being plotted on equidistant abscissæ, and an increasing multiple of 22 being subtracted from the atomic weights The principal families of the elements were shown by connecting their members by lines From these lines it was graphically shown that the values at present assigned to A and Te are three or four units too great, and it was suggested that Se may also be too high Other interesting relations were indicated between different family lines

A Simple Hydrogen Sulfide Generator J I D Hinds, University of Nashville, Nashville, Tenn

The apparatus is in one piece The acid is added drop by drop to the sulfid and when the stopcock in the delivery tube is closed the acid is driven immediately away from the sulfid and action ceases Advantages (1) the quantity of acid in generator is always small, (2) if the acid is properly added it is practically exhausted when it passes out, (3) it is cheap, economical, no waste of gas, (4) it empties itself whenever the gas is cut off, (5) the waste flows away automatically to the sink or the open air, (6) it is always ready and may be carried from place to place

Sulfite Method for Separating and Identifying Strontium and Calcium · J I D. Hinds

Principle—Barium sulfite is difficultly soluble in hydrochloric acid, strontium sulfite is difficultly soluble in acetic acid, calcium sulfite is easily soluble in both acids

1 To a small portion of the solution (1 or 2 c c) add a drop of dilute hydrochloric acid, then a few drops of a concentrated solution of sodium sulfite A white precipitate is barium sulfite and indicates barium

2 To another small portion of the solution add a little dilute acetic acid and a few drops of sodium sulfite solution and heat to boiling A white precipitate is barium sulfite or strontium sulfite or both. In the absence of barium, it can

only be strontium. If barium is present, it should first be removed with chromate ion.

3. If barium and strontium are absent, precipitate calcium with the sulfite without acid.

4. If strontium and calcium are present together, there are two methods of procedure.

(*a*) Add to a portion of the solution sodium sulfite and warm gently, not above 30°, shake well and filter. The calcium is almost completely precipitated while much of the strontium remains in solution. Boil a portion of the filtrate. The remaining strontium separates. If strontium is absent there is no precipitate or at least a faint cloud. Pour over the precipitate on the filter a very dilute solution of acetic acid and to the filtrate add ammonium oxalate. A precipitate is calcium oxalate.

(*b*) Make the solution acid with acetic acid, add sodium sulfite and boil. Be sure that acid is added in excess of that required to neutralize the sulfite solution which is alkalin by hydrolysis. The mixture should be but slightly acid. Shake well. Let stand a few minutes to settle, then filter, pouring the liquid through repeatedly until it is clear. Dilute a portion of the filtrate with an equal quantity of water and add ammonium oxalate. A precipitate is calcium oxalate.

DIVISION OF PHYSICAL AND INORGANIC CHEMISTRY

Electrical Equipment for Electroanalysis and Electric Furnace Work: FRANCIS C. FRARY.

The author described specially designed switchboards for the distribution of the current from a storage battery to a class in electroanalysis, and for the use of the individual students in the class. The boards are designed from the view point of maximum efficiency and flexibility at minimum expense.

The arrangement of a 10 K.V.A. transformer for work in the furnace-room was described and illustrated. Four secondary coils are provided, two giving 10 volts and two 20. By means of copper straps these may be connected in all possible useful combinations. Five and 10 per cent. taps on the high tension (220 volt) side of the transformer allow the increase or decrease of the voltage thus generated by 5 or 10 per cent., thus giving four possible voltages for each combination of the secondary coils. Suitable circuit-breakers are provided on both the primary and secondary sides of the transformer. Suitable measuring instruments are provided, and a large double throw double pole switch allows the bus bars in the furnace-room to be connected to either direct or alternating current.

Solubility of Oxygen at Different Temperatures in Water containing Different Amounts of Chlorine

From original experiments made with the Winkler method and experiments by Fox, using a method of direct absorption, a table has been prepared showing the solubility of oxygen at different temperatures in sea water and brackish waters containing different amounts of chlorine The results in condensed form are given above

The Work of the Chemical Laboratories of the Bureau of Mines J K CLEMENT

The chemical work is divided among a number of separate laboratories, each carrying on its own lines of work under the direction of its own chief, the whole forming a group of more or less independent units In general, the problems of the chemists are closely connected with those of the mining and mechanical engineers

The Fuel testing Laboratory is occupied mainly with the analysis and calorimetric testing of fuels, including coal, coke, lignite and peat In addition to analyzing samples of all fuels used in the boiler and gas producer tests of the bureau, ultimate analyses and calorific value determinations are made on mine samples of coal collected by the U S Geological Survey, as well as by certain state geological surveys

Fusibility and Clinkering of Coal Ash—In the use of coal under steam boilers, the property next in importance to its calorific value is perhaps the fusibility of its ash Indeed, some coals, which have a high heating value, are worthless for making steam on account of their tendency to clinker and adhere to the grate bars The relation between the fusibility and clinkering properties of coal ash and its chemical and mineralogical composition is now being investigated

Chemistry of Petroleum Technology—The bureau is making a study of the commercial bodies contained in the crude petroleums of the United States, of the methods for their separation and purification and of their economic uses The California fields have been selected for first study

Combustion Investigations—The processes of combustion in the boiler furnaces are being investigated in a furnace specially designed for the purpose.

The process of producer-gas formation is being studied from a physical chemical standpoint, and an attempt will be made to apply, on a commercial scale, the results of laboratory experiments on the rate of formation of carbon monoxide and water gas.

The Composition of Coal.—The object of this investigation of the bureau is the isolation and identification of some of the constituents of coal.

The Volatile Matter of Coal.—The quantity and composition of the gases evolved from various coals, when heated to temperatures of from 400° to 1000° C., have been determined. In the experiments which are now in progress, particular attention will be given to the influence of the rate of heating on the character of the gases produced, to the initial composition of the gases at the instant of liberation, and to the thermal decomposition of these gases during passage over heated surfaces.

Weathering and Deterioration of Coal.—In cooperation with the Navy Department, the Panama Railroad Company and the University of Michigan, the bureau is conducting an extensive series of tests on the deterioration of various coals in storage both in the open air and when submerged in fresh water and sea water.

The Accumulation of Gas from Coal.—The quantity and rate of formation of inflammable gas from freshly mined coal, at ordinary temperatures, and the rate of absorption of oxygen by the coal have been determined.

The spontaneous combustion of coal is being investigated by the bureau. Statistical information will be combined with the results obtained in the laboratory.

The Burning of Coal in Mines under a Diminished Supply of Oxygen.—The factors governing the propagation or extinguishing of fires in mines are being investigated.

Examination of Mine Gases.—Examination is made of samples from normal mine air, from the after damp following explosions, from stagnant areas and from burning areas during mine fires. Particular attention has been given to the detection of small amounts of carbon monoxide.

The Chemistry of Explosives.—Chemical analyses are made of all explosives submitted to the bureau for test, of the products of combustion of explosives, and of electric detonators, blasting caps and fuses.

Coal dust Explosions.—The two greatest sources of danger encountered in mining operations are the explosive gases given off by the coal, and the finely divided coal dust which exists throughout most coal mines. The first danger can be overcome by increasing the ventilation in the mines. Unfortunately, this increases the danger from the coal dust by the removal of its moisture.

The Use of the Blue-print in the Teaching of Industrial Chemistry FRANCIS C FRARY

Instead of the time-honored methods of showing charts or drawing diagrams of machinery on the black-board, the author recommends the use of the lantern slide and the blue-print the lantern-slide to be shown to the class, and a blue-print of the apparatus, made from the same negative as the slide, to be given to the student to paste in his note-book. Thus time is saved in the class-room, and the student has a better idea of the apparatus. The system was developed by Dean W R Appleby, of the Minnesota School of Mines, for use in the teaching of metallurgy, and the author has found it likewise helpful in the teaching of industrial chemistry and electrochemistry

Proficiency in Qualitative Analysis H C COOPER

The results of an inquiry among prominent American chemists conducted to ascertain how students can best be prepared to make reliable analyses of miscellaneous materials were reported It was the majority opinion that the students should be given rather extensive drill in the thorough qualitative analysis of minerals and technical products Since qualitative analysis is generally taught to freshmen or sophomores, praiseworthy mention was given to the plan of conducting a supplementary course in the subject for the advanced students Considerable discussion was aroused by the question of teaching students to make abbreviated analyses

Points of View in the Teaching of Industrial Chemistry JAMES R WITHROW

Defining industrial chemistry as the study of the manufacture of chemical substances and the production of commercial products with the help of chemical operations the point of view of the lecture work was taken up Each industry is considered as a problem for the solution of the difficulties of which much work has been done and much remains to be done The student is also made to analyze each of the industries with reference to operations involved, such as distillation, condensation, filtration, etc These points of view give the student the desirable attitude of mind which makes him analytically critical of the industries and also makes him scrutinize the methods used to overcome difficulties in a way that makes for increased personal efficiency With regard to the laboratory work, the usefulness of familiarizing the student with the "tools of the trade" is emphasized, but the mere requirement of such familiarity is by no means the highest object to be obtained Emphasis is laid rather on the solution of problems in the study of cost and acquiring of data for use in works experiments on the manufacture of commercial products or utilization of by-products The difficulties arising give the student a keen appreciation of the value to him of the library and all work, whether theoretical or practical, which is within his reach In a word, the work is industrial research. It shows the student how to attack problems; familiarizes him with the spirit of manufacturing chemistry, gives him the proper attitude of mind toward his science, makes him

appreciative of the labor of others, and makes him conscious of the meaning of the responsibility of industrial service

The Determination of Nitrogen in Commercial Ammoniates of High Nitrogen Content Report of the Committee on Nitrogen, Division of Fertilizer Chemists PAUL RUDNICK, chairman

Three samples were prepared, namely, dried blood, tankage and a complete fertilizer, all the nitrogen of which was derived from the same lot of dried blood Forty eight laboratories reported results by all the usual methods, including an average of 223 individual moisture determinations and 259 individual nitrogen determinations on each of the three samples

The results were grouped into tables according to the methods employed The results by the absolute or cupridoxid method were unsatisfactory and only one set of determinations by the soda lime method was received

The individual variations from the arithmetical means in the several tables were large, but the average results of the "wet combustion" methods showed a very satisfactory agreement

The Kjeldahl Gunning method gave the highest results

Special attention is called to the necessity for special precautions in the preparation and packing of samples representing shipments of these and similar commodities, in order that changes in the moisture content may be reduced to a minimum

THE CHICAGO ACADEMY OF SCIENCES

THE annual meeting of the Chicago Academy of Sciences was held January 10, 1911, at which time Dr T C Chamberlin was reelected president; Mr A. L Stevenson, first vice president; Dr U S Grant, second vice president, and Dr Wallace W. Atwood was again made secretary The reports of the officers of the academy showed that during the past year the work and the influence of the academy have become more strongly educational The scientific collections and exhibits in the museum are carefully maintained and will always be available for specialists to study, but the museum is rapidly taking on a distinctly educational policy and the exhibits are being appropriately altered or replaced

The loaning of museum material to the schools has continued, lecture courses or lessons have been offered to the children who have come as delegates from their respective school rooms, several illustrated lectures have been given at the schools, instructional courses open to the teachers of nature study have been offered and university credit courses have been conducted for those wishing to systematically pursue courses of instruction

It is evident from the work, both of the museum and of the instructional courses given in cooperation with the work of the museum, that the academy is rapidly assuming a conspicuous place among the educational institutions of Chicago The expressions of appreciation which have come to us from the superintendent and district superintendents of the public schools have been most encouraging The expressions of appreciation which reach us from the principals and teachers more immediately engaged in the educational work of the North Side, are enthusiastic in praise and appreciation of the influence which the academy is having

The opportunities for the academy lie far beyond anything which we have yet realized The North Side of Chicago is distinctly lacking in any public institution which is actively assisting in the educational work of the schools and offering instructional courses for adults. The work of the academy should be consistently restricted to the utilization of the scientific data and material in educational work, but the opportunities within that field are among the most attractive that are open to any educational workers

It is, indeed, somewhat surprising to see how easily the academy may become an effective instrument in the educational work of the city There seem to have been so many gaps, so many places where we may fit in, and the regret is that we have not better facilities at the building and a larger force who may put their personal efforts into the promotion of science work among the young people and teachers of the city.

The institution has outgrown its present quarters and the demands upon it and the opportunities open to it indicate that the additional building which was originally planned for the institution should now be erected We need a new building with an auditorium which has a seating capacity of five to eight hundred for various meetings and lectures Class rooms, laboratories and children's work rooms in which courses of instruction may be conducted, should be provided and a children's museum should be placed in this additional space

WALLACE W ATWOOD,
Secretary

SOCIETIES AND ACADEMIES

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 688th meeting of the society was held on January 28, 1911, President Day in the chair Three papers were read

Integers Useful in Computing Square Roots of Numbers DR R S WOODWARD, of Carnegie Institution of Washington

This paper is a continuation and extension in application of the paper on "A Method of Precision for Computing Square Roots of Numbers," presented by the speaker at the 680th meeting of the society This paper will later appear in full in the publications of the American Mathematical Society

A Method for Grading the Results of Tests in Judging DR LYMAN J BRIGGS, of the Department of Agriculture

This paper describes a rational method of grading student tests in judging such as are now extensively held in agricultural schools These tests consist in determining how nearly five or more objects can be arranged in the correct order of excellence Since adjacent objects, when the series is correctly arranged, differ in excellence in varying degree, it becomes necessary to take cognizance of this in grading the arrangements made by different students Furthermore, since there are seven hundred and twenty possible arrangements of six objects, the grading of the different arrangements becomes hopelessly complicated unless some rational system is adopted

The system proposed is based upon the three following principles

1 Any arrangement of objects departing from the correct order is brought about through the exchange of adjacent objects

2 The error due to transposing two adjacent objects from their correct order is directly proportional to the difference in excellence of the two objects transposed.

3 An erroneous arrangement is penalized in the exact proportion that the error bears to the greatest error that can be made in the series under consideration

In employing this system of grading the instructor first decides upon the relative difference in excellence between adjacent objects in the

series when arranged in correct order This virtually amounts to distributing the objects properly along some numerical scale taken as a scale of excellence Each student's arrangement of the objects is then penalized in proportion to the difference in excellence of the objects exchanged and to the number of exchanges necessary to bring about the correct arrangement The penalty can be placed upon a percentage basis, if desired, by determining the ratio of any observed errors to that represented by completely inverting the series The system can be applied to any series either with uniform or non uniform intervals, it requires no tables, and it can be used with any number of objects

The Measurement of Two Primary Base Lines with Invar Tapes Mr WILLIAM BOWIE, of the Coast and Geodetic Survey

There are several types of base apparatus which have been used successfully in recent years by the Coast and Geodetic Survey They are (1) the secondary apparatus, a monometallic multiple bar system, (2) the duplex apparatus, a bimetallic multiple bar system, (3) steel tapes of 50 and 100 meters in length, and (4) nickel steel or invar tapes of 50 meter lengths

The secondary bars and the duplex bars gave very accurate results, yet their operation was more expensive than tapes Tests made at the Holton base in 1891, by Professor R S Woodward, indicated that primary base lines could be successfully measured with steel tapes, and they were used in connection with the duplex bars in 1900 in the measurement of nine bases along the 98th meridian In 1906 six primary bases were measured with both steel and invar tapes It was found that the measurement of a base with tapes occupied about twenty days while the measurement of a base with the bars had usually taken several months

As the nickel steel or invar base tapes were satisfactory in the measurement of bases in 1906 it was decided to use them in measuring two primary bases, one at Stanton, Tex, and the other at Deming, N M, on the Texas California arc of primary triangulation in 1909–10 These bases were measured by the triangulation party working in the vicinity Owing to the small coefficient of expansion of the invar metal, it is possible to do the measuring in the hours of daylight The coefficient of expansion of the tapes used on the primary bases by the Coast and Geodetic Survey is only about one twenty-fifth that of steel

Four invar tapes, each 50 meters in length, were carried to the field and three of them were used in the measurement One was held in reserve for use in case of accident to one of the other three The tapes were standardized at the Bureau of Standards before and after the measurement of each base The Stanton base has a length of 13,193 meters The size of the party on this base was two observers and seven other men One of the observers was Mr J S Hill, the chief of party During the actual measurements only six persons were engaged

A very simple tape stretcher was used on the measurements of the Stanton and Deming bases, its weight being only eighteen pounds The adoption of this simple and light stretcher is a step in the right direction, for the amount of measuring accomplished by a party in any one day depends largely upon the endurance of the man carrying the forward stretcher

A base 15,554 meters in length was measured in the vicinity of Deming, N M, in 1910, by the same party that measured the Stanton base in the previous year The measurement of the Stanton base occupied the party seventeen days, while thirteen days were required for the measurement of the Deming base The probable error of the measurement of the Stanton base was one part in 2,560,000, and the probable error for the Deming base was one part in 1,960,000

Some of the conclusions which were drawn from the measurement of these two bases are (1) the 50 meter tape was found to be both convenient and satisfactory, confirming the conclusions based upon previous tape work by the Coast and Geodetic Survey, (2) invar tapes with measurements made in daylight or at night give results which are as accurate as those obtained by the duplex base bars; (3) it is not necessary to standardize the invar tapes in the field; (4) owing to their small coefficients of expansion invar tapes give more accurate results than steel tapes, (5) with proper care during measurements in the field, the invar tape does not change appreciably in length While not so elastic as steel, yet it is sufficiently strong to withstand the ordinary shocks due to excessive tension

It is possible that the invar tape will not find favor with the surveyor and engineer, for general use, on account of its low elasticity, but it has proved to be a most satisfactory apparatus for the measurement of primary base lines by the Coast and Geodetic Survey.

Secretary

THE GEOLOGICAL SOCIETY OF WASHINGTON

THE 237th meeting of the society was held at the Cosmos Club on Wednesday evening, January 11, 1911

Regular Program

Desert Pavements and Analogous Phenomena E E FREE

Where wind scour acts on unconsolidated desert materials pebble pavements are of common occurrence Such occurrences have been described by Blake,[1] Tolman[2] and others As a result of similar wind scour the surface sand of stable dune areas is often coarser than that underneath Analogous pavements are occasionally produced by water action

Nonnezoshe—the great Natural Bridge of Southern Utah JOSEPH E POGUE

Southeastern Utah boasts four natural bridges, the Owochomo, the Kachina, the Sipapu and Barohoini (Piute for rainbow) or Nonnezoshie (Navaho for stone arch), each of which surpasses in size the well known Virginia natural bridge The first three of these have been called by commonplace personal names, but the above names are original Indian ones and are far preferable The largest and most southerly of the four, the Rainbow Bridge, was visited on July 26, 1910, by a U S Geological Survey party consisting of H E Gregory, in charge, John Wetherell, K C Heald and the writer This imposing structure is situated in San Juan County, in a wild and well nigh inaccessible part of the Navaho Reservation, just four miles north of Navaho Mountain and near the junction of the San Juan and Colorado rivers

The La Plata (Jurassic?) sandstone, here 1,200 feet or more in thickness, is deeply dissected by a labyrinth of tortuous canyons, and near the mouth of one of these the bridge is found A towering arch, rainbow-shaped and of model symmetry, rises from a ledge on one side of the canyon, and spanning a small stream, joins the opposite wall on its downward bend The opening measures 267 feet in height by 278 feet between abutments, but the distance from stream bottom to top of arch totals 309 feet, while the keystone portion is only 42 feet thick by 33 feet wide The arch is carved from a buff colored massive phase of the La Plata sandstone, and represents an opening, enlarged and shaped by desert weathering, through which the stream originally cut off one of its meanders The abandoned meander remains as a proof of this origin

The bridge was discovered on August 14, 1909, by W B Douglas, of the U S General Land Office, with four assistants, and Byron Cummings, of the University of Utah, with three students, under the guidance of John Wetherell and two Navaho Indians It has subsequently been set aside as a national monument and represents the largest and most graceful structure of its kind thus far known

Criteria for an Unconformity in the so called Laramie of the Raton Mesa Coal Fields of New Mexico and Colorado W T LEE

During the summer of 1910 the unconformity in the coal bearing rocks of the Raton coal field of New Mexico, first announced in 1908 and published upon the following year, was traced around the Raton coal field in New Mexico and the Trinidad coal field in Colorado, an area extending about ninety miles along the east front of the Rocky Mountains and stretching eastward to a maximum width of fifty miles The evidences of unconformity may be grouped under two general headings, stratigraphic and paleontologic

The formation below the unconformity is coal-bearing and varies in thickness from about 450 feet to 0 The formation above the unconformity is likewise coal bearing and is marked by a constant basal zone of conglomeratic sandstone The relation of the basal conglomerate of the upper formation to the beds below leaves little room for doubt that the variation in thickness of the lower formation is due to erosion In at least four places the lower coal bearing formation is wanting and the basal conglomerate of the upper one rests upon older rocks This basal conglomerate contains pebbles of coal which must have come from the lower coal formation, pebbles of conglomerate which could come only from the Dakota, stratigraphically about 3,500 feet below, or from some formation still older, pebbles of red sandstone which could come only from the red beds, the top of which is about 4,000 feet below, pebbles of horn corals and fossiliferous cherts, such as are now found in the Carboniferous rocks west of the coal fields, about 18,000 feet below; and a variety of metamorphic and igneous rocks, including crystals of feldspar supposed to come from the crystalline complex of the mountains Apparently these pebbles prove that after the earlier coal measures were formed the mountains west of the Raton Mesa region were elevated and the upturned stratified rocks, having a measured

[1] Rept Pac Ry Surv, 5 230, 1856

[2] *Jour. Geol*, 17 149–151, 1909

thickness of more than 18,000 feet, were eroded before the basal conglomerate of the upper coal measures was laid down

The paleontologic evidence is almost wholly from the fossil plants, which apparently indicate a time break of considerable duration Large collections were made from both formations and F H Knowlton, who is studying them, states that they contain two distinct floras However, correlations are withheld pending the final study of these fossils

The data collected apparently prove that after the lower part of the coal bearing rocks in the Raton Mesa region, heretofore referred to the Laramie, had been consolidated the mountains to the west were uplifted and part of these rocks, together with all of such younger beds as may have been deposited, were eroded away before deposition of sediments was resumed in this region The general conclusion is reached that the so called Laramie of the Raton Mesa is divisible into two distinct formations separated in time by a period of considerable duration.

ROBERT ANDERSON,
Secretary

THE TORREY BOTANICAL CLUB

THE meeting of December 13, 1910, was called to order at the American Museum of Natural History at 8 30 P M, Tuesday, December 13, 1910, with President Rusby in the chair One hundred people were present

The scientific program consisted of an illustrated lecture by Dr Marshall A Howe on "A Visit to the Panama Canal Zone"

The visit described by the speaker occurred in December, 1909, and January, 1910, and was undertaken under the auspices of the New York Botanical Garden, with the special object of studying and comparing the marine floras of the Atlantic and Pacific oceans, here within less than fifty miles of each other

The marine algæ proving unexpectedly scarce, especially on the Pacific side of the isthmus, there was considerable opportunity for taking photographs of general botanical interest and the lantern slides shown illustrated chiefly some of the more striking features of the land flora of the Canal Zone, such as the numerous native palms, the vegetation of the extensive fresh water swamps between Colon and Gatun, the swampy forests bordering the Chagres River, and the flora of the rocky islands of Panama Bay A report covering some of these features of the lecture was published in the *Journal of the New York Botanical Garden* for February, 1910

The speaker justified a somewhat extended discussion of the Panama Canal and its history by the general interest in the subject both here and on the isthmus Among the photographs shown were several of the Atlantic and Pacific entrances to the canal, the Gatun locks, a flood on the Chagres River, the Culebra Cut, the Ancon Hospital and the Taboga Sanitarium. The success of modern sanitary methods in combating yellow fever and malaria was especially dwelt upon. The speaker alluded also to incidents of interest in the romantic early history of the isthmus and in the building of the Panama Railroad. Photographs of the ruins of Old Panama, located about five miles east of the present city, were also shown

SERENO STETSON,
Secretary pro tem

THE AMERICAN CHEMICAL SOCIETY
NEW YORK SECTION

THE fifth regular meeting of the session of 1910–11 was held at the Chemists' Club on February 10

The chairman spoke of the great loss to the society in the death of Professor Kinnicutt and called upon Dr Clifford Richardson to make a few remarks about his career Professor Morris Loeb paid a further tribute to Professor Kinnicutt and then, passing from a matter of deep regret to one of rejoicing, spoke of the festivities connected with the opening of the new chemists' building in New York, beginning March 17

The chairman read a letter of regret from Professor Boltwood, who was unable to be present to read a paper on "Radio-chemistry," announced on the program He then called upon Professor A T Lincoln, of Rensselaer Polytechnic Institute, who presented a résumé of recent work on the subject of solutions under the title "The Hydrate Theory."

The rest of the evening was devoted to a symposium on milk, which comprised the following subjects:

"Determination of Total Solids in Milk," Paul Poetschke, of the Lederle Laboratories

"Milk Costs," W E J. Kirk, medical adviser to the Borden's Condensed Milk Company

"Raw and Pasteurized Milk and Milk Serums," Edward Gudeman, of Chicago.

THE INFLUENCE OF ASTRONOMY ON MATHEMATICS

THERE are probably many reasons why the members of the eleven sections of the American Association, representing at least fifteen sciences, have united in a single society. One of these is undoubtedly that the mingling of men of varied chief interests, points of view and methods of work has at least a tendency to correct those intellectual provincialisms which are characteristic of isolation, and to show how wide and how rich is the field of scientific activity. While it is unquestionably advantageous on some occasions for narrower groups of men whose interests are more nearly common and whose scientific activities run more nearly in the same channel, to meet apart for the consideration of their own special problems, yet on the whole the benefits to be derived from occasional joint meetings are so great that it is earnestly hoped the American Association will prosper in the future even more than it has prospered in the past, and that the individual scientific societies will not cease to cooperate with it.

If it is agreed that there are real benefits to be derived from an association of many distinct scientific societies, it will equally be granted that some advantages may be obtained from a meeting where so many points of view, modes of thought, and methods of investigation are represented as among the members of Section A. These diverse, and in some cases conflicting, points of view have arisen from the narrow specialization of recent times, and from the fact that the bounds of our knowledge have extended more rapidly

than our individual capacities for encompassing them Historically, astronomy and mathematics have been most intimately related In antiquity the roll of the celebrated masters in one of these sciences would almost exactly coincide with that in the other, and in more modern times the names of Newton, Euler, Lagrange, Laplace, Gauss, Cauchy, Poincaré and many others, which are equally honored by both astronomers and mathematicians, show how much they still have in common It is for this reason that in accepting our secretary's invitation to present a paper before you I have chosen to lay emphasis on these close relations, and in doing so I apologize only because I am so poorly prepared adequately to treat so worthy a theme If you will permit the interjection of a purely personal remark, I should like to state that it is not solely because of the close relations of astronomy and mathematics that I have chosen my topic, but because a most fortunate experience has taught me that the lack of sympathy, if not of respect, for the efforts in one domain by workers in another is due almost wholly to a lack of acquaintance with them I refer to the fact that for fifteen years I have been intimately associated with one of the former presidents of the American Association, with the present president, and with the vice-president of Section A The first has taught me how the mind of the naturalist works, how vivid and constructive is his imagination, how fertile he is in inventing hypotheses, how exhaustively he gathers his data, and how impartially he weighs evidence where prejudices easily might have influence, the second has shown me how keen are the intuitions of the physicist, how his quantitative estimates almost rival in accuracy mathematical calculations, and how his marvelous instruments increase the delicacy of our senses a million fold at a single leap, making it unnecessary for us to wait inconceivable ages for their evolution to that degree of perfection, the third has revealed to me how beautiful are the logical structures which can be built on independent and consistent hypotheses, how keen are the pleasures in establishing all the harmonious relations involved in a mathematical theory, and how great is the satisfaction in the discovery of that which is common and fundamental to many apparently distinct theories Here I confess my profound and equal respect for all these phases of scientific activity, and my belief that they are all of fundamental importance If in my attempts to accomplish something I follow more nearly along the line of one than another, it is because I believe that on account of personal tastes and training I am less likely to fail there than in the others

There does not seem to be a disposition on the part of any one to limit the field of activity of the astronomer He is supposed not only to know how to measure the distances, to calculate the motions, and to determine the composition of the heavenly bodies, but also to understand fully those complex factors which produce the weather changes, to be familiar with certain mysterious forces which bring good or bad luck to an individual, to have reliable data respecting the location of heaven and its antithesis, and to be an expert on the questions of the freedom of the will, the existence of an infinite being, and the immortality of the soul But the matter is quite different in the case of the mathematician Often he is criticized for busying himself with pure fictions of the mind rather than with the so-called actualities of physical problems It is no more passive antagonism, for there are many places in these halls to-day where a storm can be raised

by starting a discussion of imaginary numbers, hyperspace, or the non-euclidean geometries. It is easy to find men who will mark out the regions within which mathematicians should exercise their powers It is an interesting psychological phenomenon that a specialist who has spent many years on a subject and has become a recognized authority in it seldom, if ever, will make any definite and general statement in regard to it, yet often he will not hesitate to make sweeping dogmatic assertions respecting things entirely outside his line, for example (to use a harmless illustration), respecting the merits of the tariff or the crime of seventy-three Even those who have been expert in mathematics have differed much among themselves respecting what should be its highest aims Fourier, in reporting on the work of Jacobi to the Academy of Sciences, said that natural philosophy should be the principal object of the meditations of mathematicians In the introduction to his theory of heat referring to analysis he wrote "there could not be a language more universal and more simple, more exempt from errors and obscurities, that is to say, more worthy of expressing the invariable relations of natural objects Considered from this point of view, it is coextensive with nature itself, it defines all the sensible relations, measures the times, the spaces, the forces, the temperatures, this difficult science is formed slowly, but it retains all the principles it has once acquired. It grows and becomes more certain without limit in the midst of so many errors of the human mind." Replying to the reproach of Fourier, Jacobi, in a letter to Legendre, said: "It is true that M Fourier had the opinion that the principal end of mathematics was the public utility and the explanation of natural phenomena, but such a philosopher as he is should have known that the unique end of science is the honor of the human mind, and that from this point of view a question of number is as important as a question of the system of the world" Gauss agreed, for he said that mathematics is the queen of the sciences, and that arithmetic is the queen of mathematics

Obviously it is just that the astronomer should allow the mathematician all the latitude in defining the limits of mathematics that he himself would desire if he were permitted to mark out the borders of the field of astronomy It would be considered unwarrantable interference and an evidence of hopeless ignorance if any group of men should attempt to make astronomers confine themselves to those phases of their subject which are immediately useful to a busy world If astronomy were limited simply to those parts which are necessary for time service on the land and the use of navigators on the sea, if it were necessary to abandon those mathematical theories of the motions of the planets and satellites which are in all respects the most perfect examples in natural science of harmony between theory and observation, if it were no longer permitted to use our powerful instruments in observing the peculiarities of the planets and the sun, if we were compelled to discontinue our investigation as to their origin and evolution, if we were under obligations to give up the spectroscope forever, and if we were forced to forego all further attempts to sound the almost boundless depths of the sidereal system and unravel its mysteries, if astronomy were put under these restraints, I say, then most of those incentives which in all the history of astronomical science have produced the rarest examples of devotion to ideals and the pursuit of knowledge would be removed Astronomers do not admit the right of a partially informed

world to prescribe the boundaries for their activities, nor do they in turn feel qualified or even inclined to impose any limitations upon the mathematicians. They could not even say what kinds of mathematics will be of use to themselves or to other branches of physical science. To take an example old enough to be understood in correct perspective, the interval between the discovery of the properties of the conic sections by Menæchmus and their first practical use by Kepler was 2,000 years, or more than nine times that which separates us from Newton. Astronomers will admit, then, that if the sole purpose of mathematics were to serve the other sciences, it would not be safe to circumscribe it by any boundaries. And most of them, I think, will go much further and join me in the sentiment that mathematics, altogether apart from its uses in other subjects, has a right to exist, that it is a part of the universe of ideas which to a thinking being is no less real and important than the physical universe, that its proportions and its symmetries which find perfect expression in its wonderful symbolism are, in satisfying the esthetic tastes, on a level with the fine arts, and that the process of drawing its conclusions calls for an exercise of the best and highest faculties we possess. If we were required to describe the proper field of mathematics we might say simply that it includes at least all that which all mathematicians together claim belongs to it.

Having admitted the breadth of mathematics, we have to consider what part of it has had at least its initial inspiration in astronomy. It might, perhaps, be argued with a good deal of justice that all of mathematics has originated directly or indirectly in the experience of the human race, that our capacity for those particular modes of thought which are essential to its development have evolved under the stimulus of the physical world. It is significant, at any rate, that there is such wonderful harmony between the results obtained by mathematical processes and our experiences. But it is not the purpose here to make any such claims, or to become involved in the difficulties of metaphysical discussions. No thesis has been laid down which it is necessary to defend, and no claim that astronomy has had an important influence on mathematics will be filed except where the evidence is perfectly clear and conclusive.

It was noted in the beginning that in ancient times the astronomers were almost invariably also mathematicians and reversely, and consequently that it is difficult to separate the two sciences of that time so as to determine exactly the influence which each had on the other. But there is one case in which the demands of astronomical problems certainly stimulated the development of a mathematical theory. Trigonometry was invented by Hipparchus, who was the most eminent Greek astronomer, both as a practical observer and as a mathematician. He determined the length of the year correctly to within six minutes of its true value, the obliquity of the ecliptic to within five minutes of arc, the annual precession of the equinoxes to within nine seconds of arc, the distance of the moon to within one per cent of its value, the mean motions of the sun, moon and known planets, the changes in the moon's orbit, he made a catalogue of the fixed stars, etc. There is every reason to believe that these astronomical problems were those in which he was chiefly interested, and they made it necessary for him to develop trigonometry, and especially spherical trigonometry. His work was completed by Gauss nearly 2,000 years

latter in connection with the solution of the same problems

We shall not, however, get any comprehensive view of the relations of astronomy and mathematics by citing, without some classification, isolated examples where the latter is indebted to the former Such a procedure will give us no idea of the reasons for any of the great movements in mathematical thought Moreover, the mathematical theories are so interwoven that it is difficult to pick out individual branches and to discuss their origins without being at least very incomplete Therefore we shall content ourselves with broad classifications of mathematics, and to statements, with illustrations, of those parts where the practical problems of astronomy have had important influences

Mathematics may first be divided into the metrical and the non-metrical branches The former are vastly more important than the latter, or, since it is perhaps wise to avoid passing judgment as to what is important, the metrical branches have at least an enormously greater literature than the non-metrical Recognizing the fact that there is much of a non-metrical character in those subjects which are regarded as being on the whole metrical in nature, and not wishing to insist on the possibility of making an absolute division on this principle, an examination of the Royal Society Index covering publications in mathematics from 1800 to 1900 shows that probably not one part in forty has been devoted to non-metrical mathematics While there are certain non-metrical aspects of some astronomical problems, it would not be fair to claim that astronomy has had any essential part in inspiring these branches of mathematics.

Now considering only the metrical branches of mathematics, we may divide them into the mathematics of the continuous and the mathematics of the discrete Here the problem of actually effecting the division is even more difficult than in the preceding case, for there is more intermingling and there seem to be more debatable points In spite of these difficulties the mode of division is attached to certain fundamental characteristics either of the subject matter or of the processes employed The ordinary theory of numbers is an example of the mathematics of the discrete The theory of ordinary equations, for example, linear equations, may be considered as an example of the mathematics of the discrete or the continuous, according as the coefficients are regarded as discrete numbers or continuous functions of certain parameters In such cases where the ideas of continuity are not essential to the formulation and treatment of the problems, they will be considered as belonging to the mathematics of the discrete All those branches of mathematics in which continuity is an essential feature, as, for example, those involving derivatives, constitute the mathematics of the continuous

On the whole, the problems of astronomy have not given rise to the mathematics of the discrete While the physical universe seems to be made out of discrete things—atoms, corpuscles, units of electricity—it changes continuously from one state to another Since a large part of the problems of the natural sciences relate to changes of position or state, such as the motion of a world or the evolution of an animal, this continuity is forced into the foreground in the applications of mathematics to physical questions Consequently, in seeking for places where astronomy has made real contributions to mathematical theory we may restrict our search to the mathematics of the continuous If there are no other subjects which have made similar contributions, we have at once the

answer to the question of the extent of its influences. Since astronomy is more thousands of years old than most of the other natural sciences are centuries, it has naturally called forth most of those mathematical processes which have been needed in the others. About the only other natural science which has given rise to important mathematical theories is physics, which has forced attention to certain classes of partial differential equations and to the statistical methods employed in the kinetic theory of gases. Another important advantage astronomy has enjoyed is the delicate character of many of its observations and the high degree of precision of many of its theories. These have naturally directed attention to the questions of logical rigor. It is probably known to most of the members of this section that the numerically most perfect theory in all the range of physical science in all time is the lunar theory of our retiring vice-president. But the mathematics of the continuous has not been inspired by astronomy alone, or even by all the physical sciences together. In geometry the questions of tangents and areas have involved the same principles and have given rise to some of the same methods. Consequently we can conclude only that the problems of astronomy have given rise to some of the theories of the mathematics of the continuous.

It will perhaps be worth while to descend for a few minutes from the general to the particular, and to consider more concretely what contributions astronomy has actually made to mathematics. It is agreed by all that the invention of the calculus was one of the most important steps ever made in mathematics. It was founded first by Newton and a little later independently by Leibnitz. The work of either was sufficient to open the way to all that which has followed the invention of this important branch of mathematics. Newton's ideas were largely inspired by the consideration of physical phenomena, as is shown by the terminology and notation he used as well as by the problems to which he applied his methods. He spoke of *fluents* and *fluxions* and used the time as the independent variable, though he knew this was not essential. It simply indicates the stimulus of his ideas. On the other hand, Leibnitz used the terminology of geometry and seemed to have arrived at his ideas of derivatives through the consideration of tangents to curves. These differences constitute an internal evidence of the independence of the work of Newton and of Leibnitz.

The history of the application of the calculus in the century following its discovery constitutes one of the most glorious records of the achievements of the human mind. Mathematicians had a new method of enormous power and the greatest generality, while the laws of motion and the law of gravitation were the keys that unlocked a new universe to them. The work of Clairaut, d'Alembert, Euler, Lagrange and Laplace was one succession of triumphs. With the enthusiasm of explorers they traversed the worlds Newton and Leibnitz had opened, and with Laplace it was supposed the discoveries in them were about exhausted. The point to be emphasized here is that whatever may have been the origin of the calculus, its evolution into the larger domain of analysis in the century following its invention was due almost entirely to the stimulus of physical, and in particular astronomical, problems. There does not seem room for doubt that the very important place which analysis now occupies in mathematics is to a large extent due to its applications to astronomy.

Astronomy not only turned the attention of mathematicians to analysis, but it often determined the precise form their theories

should take. Consider, for example, analytic differential equations. There are five distinct methods of developing their solutions—as power series in the independent variable, as power series in parameters, as limits of equations of finite differences, by successive approximations, and by successive applications of the variation of constants—all of which were devised under the pressure of practical astronomical problems and were applied successfully many years before the conditions of their legitimacy were fully established by mathematical methods. A more recent example is Hill's treatment of the linear differential equation having simply periodic coefficients, the properties of whose solutions were inferred by him from the properties of the motion of the moon. The problems connected with an infinite number of simultaneous homogeneous linear equations also arose in Hill's lunar theory. Poincaré's researches in the problem of three bodies led him to the discovery of many new properties of the solutions of differential equations. The question of the legitimacy of the series used in celestial mechanics, particularly when applied for long intervals, has forced a consideration of the problem of determining what classes of divergent series may be used and what conclusions may be drawn from them, and the same question has stimulated investigations of other modes of representing solutions, particularly as sums of polynomials in the independent variable, having wider domains of validity. In this direction Painlevé has achieved the most important results, and has shown how to construct functions which represent the solution of the general problem of n bodies so long as there are no collisions. If the forces were repulsive instead of attractive the developments would be valid indefinitely. But as Laplace said "nature does not care for analytical difficulties", in fact, it fills the way of the mathematician with them. As a partial recompense for the difficulties it raises it often suggests methods for overcoming them, and these methods being made general in the symbolism of mathematics constitute new processes often applicable in many other directions.

One of the recent movements in mathematics is in the application of the postulational method. It consists in postulating the existence of certain elements which are wholly without properties except as they are imposed by the postulates and the explicitly stated axioms. The postulates and their implications constitute the theory. It is not to be supposed that the postulates are laid down at random, or even on any simple principle of their individual and separate characteristics. The sole guide is that taken together they shall yield as consequences certain relations which are in advance in the consciousness of the investigator, the additional implications are the contributions which the developed theory makes. I do not know why there has sprung up the recent interest in this method, but it is fundamentally the method used in natural science. The experiences are the certainties given in advance which must be implications of the theories. The atoms, corpuscles, units of electricity, etc., are the postulated elements. The theories are the postulated relations among the elements. If we let $a_1, \ldots, a_n$ represent the experiences, $x_1, \ldots, x_m$ the postulated elements, then we shall have

$$f_i(x_j) = a_i,$$

where the f_i are the theories. If one of these relations fails to hold it is necessary to modify the x_j, or the f_i, or both, and it is easy to cite examples from the history of science illustrating all these possibilities. The recognition of the fundamental iden-

tity of the process of constructing theories in the realms of natural science and of developing mathematics by the postulational method will undoubtedly be of great value to the former in showing what is really essential, and to the latter in inspiring almost endless points of view.

It is not necessary to cite more examples to show that mathematics owes much to astronomy, especially in the field of analysis. If it were proper to strike a balance it could probably be shown that the debt has been more than repaid, but in these unselfish sciences the privileges of foreign service are cherished as much as the treasures of domestic achievements, and therefore we content ourselves with the recognition of the interrelations.

In closing I may point out the truism that these interrelations are not limited to astronomy and mathematics. It is to the glory of astronomy that in it were initiated the two most fundamental intellectual movements in the history of mankind, viz., the establishment of the possibility of science and of the doctrine of evolution. Our intellectual ancestors in the valleys of the Euphrates and the Nile and on the hills of Greece looked up into the sky at night and saw order there and not chaos. By painstaking observations and calculations they discovered the relatively simple laws of the motions of the heavenly bodies, whose invariable and exact fufilment led to the belief that the whole universe in all its parts is orderly and that science is possible. In the modern world this conclusion is so commonplace that its immense value is apt to be overlooked, but a study of the superstitions and the hopeless stagnation of those portions of mankind which have not yet made the discovery gives us some measure of its worth. The modern supplement to the conception that the universe is not a chaos is that not only is it an orderly universe at any instant, but that it changes from one state to another in a continuous and orderly fashion. This doctrine that science is extensive in time, as well as in space, is the fundamental element in the theory of evolution and the completion of the conception of science itself. The ideas of evolution in a scientific form were first applied to the relatively simple celestial phenomena. More than a century before the appearance of Darwin's "Origin of Species," and the philosophical writings of Spencer, another Englishman, Thomas Wright, published a book on the origin of worlds. Laplace's nebular hypothesis gave the geologists a basis for their work, which in turn paved the way for that of Darwin. For half a century now the doctrine of evolution has been a fundamental factor in the elaboration of all scientific theories, and its influence has spread to every field of intellectual effort. It has been the good fortune of mankind that his skies have sometimes been free of clouds and that he has been able to observe those relatively simple yet majestic and impersonal celestial phenomena which have not only led to so important results as the founding of science and the doctrine of evolution, but have strongly colored his poetry, philosophy and religion, and have stimulated him to the elaboration of some of his most profound mathematical theories.

University of Chicago

STATISTICS OF GERMAN UNIVERSITIES

The twenty-one German universities show an enrollment for the winter semester of 1910–11 of 54,822 students, as against 53,407 students last winter. During the past five years there has been an increase in registration of no less than 12,482 students. Curiously enough, the winter enrollment exhibits a decrease, although only of a few students, against the previous summer semester, in which

54,845 students were enrolled. The number of women students has grown from 211 five years ago to 2,418 this winter. There has been an increase in the number of students of medicine, philology and history, pure science, and Protestant theology, and a small gain in the number of students of Catholic theology, while there has been a decrease in the number of law students and in the students of dentistry and pharmacy. By faculties and groups the students were distributed as follows: Protestant theology, 2,535 (as against 2,820 in the winter semester of 1909–10); Catholic theology, 1,760 (1,698); law, 10,890 (11,317), medicine, 11,240 (10,135), dentistry, 1,146 (1,395), philosophy, philology and history, 15,525 (14,593); pure science, 7,914 (7,349), pharmacy, 954 (1,279), agriculture, 2,546 (2,085), forestry, 171 (129), veterinary medicine, 141 (107).

So far as the individual universities are concerned, those of Prussia show a larger increase than those of Bavaria and Baden, the ten Prussian universities having enrolled 28,675 students as against 27,244 last year, whereas the three Bavarian universities show an increase from 9,042 last winter to 9,842 this winter, and those of Baden from 4,101 students to 4,254 students; the remaining six German universities have increased their clientele from 11,980 to 12,552 students. The three largest universities (Berlin, München and Leipzig) alone enrolled no less than 39 per cent. of the total German student body, Berlin remaining at the top with an enrollment of 9,686 students, as against 9,242 last winter. This is followed by the University of München with 6,905 students (6,587 last year). The remaining universities range in the following order: Leipzig, 4,900 (4,761); Bonn, 3,846 (3,652); Halle 2,661 (2,393); Breslau, 2,454 (2,405); Freiburg, 2,246 (2,167); Göttingen, 2,283 (2,230), Strassburg, 2,067 (1,995); Münster, 2,047 (1,906); Heidelberg, 2,006 (1,934); Marburg, 1,981 (1,878); Tübingen, 1,883 (1,760); Jena, 1,637 (1,496); Kiel, 1,439 (1,290); Würzburg, 1,425 (1,424); Königsberg, 1,380 (1,367); Giessen, 1,249 (1,261); Erlangen, 1,011 (1,121), Greifswald, 948 (881), and Rostock, 816 (707).

The figures show that all the universities with the exception of Erlangen, Wurzburg and Giessen have increased their attendance, the smallest gains having been made by Göttingen, Konigsberg and Breslau, the largest (in percentage) by Halle, Kiel, Jena, Tübingen and Rostock. Since last winter Breslau has been passed by Halle, Gottingen by Freiburg, Heidelberg by Munster, Wurzburg and Konigsberg by Kiel.

In addition to the 54,822 matriculated students, 3,528 men and 1,772 women are enrolled this winter as auditors, giving a total of 60,122 individuals receiving instruction at the German universities, the largest number in the history of German higher education.

RUDOLF TOMBO, JR.

COLUMBIA UNIVERSITY

MEMORIAL TO CHARLES OTIS WHITMAN

VOLUME 22 of the *Journal of Morphology* will be a Charles Otis Whitman Memorial Volume. This volume was originally intended as a testimonial by former students and colleagues to the founder of the *Journal of Morphology*, Professor Charles Otis Whitman. In view of his untimely death it becomes a memorial volume. In addition to a large number of scientific papers by Professor Whitman's students and associates, illustrated with numerous plates and text figures, it will contain a biographical sketch with portraits of Professor Whitman. The edition of this volume will be sufficient to supply special orders in addition to the regular subscriptions to the *Journal of Morphology*. The contents will be as follows:

"The Sex Cells of *Amia* and *Lepidosteus*," B. M. Allen.

"Male Organs for Sperm-transfer in the Crayfish, *Cambarus affinis*, their Structure and Use," E. A. Andrews.

"Vertebrate Cephalogenesis." 3. "*Amphioxus* and *Bdellostoma*," Howard Ayers.

"On the Bilaterality of the Pigeon's Egg, a Study in Egg Organization," G. W. Bartelmez.

"The Regulatory Process in Organisms," C. M. Child.

"Cell size and Nuclear Size," E. G. Conklin.

"Oviposition Induced by the Male in Pigeons," Wallace Craig.

"The Life History of the *Scolex polymorphus* of the Woods Hole Region," W. C. Curtis.

"The Transplantation of Ovaries in Chickens," C. B. Davenport.

"On the Regular Seasonal Changes in the Relative Weight of the Central Nervous System of the Leopard Frog," Henry H. Donaldson.

"Spermatogenesis in the Arenicolidæ," E. R. Downing.

"Reproductive Activities of the Squid," Gilman A. Drew.

"Modifications in the Testes of Hybrids from the Guinea and the Common Fowl," M. F. Guyer.

"Some Problems of Cœlenterate Ontogeny," C. W. Hargitt.

"Minimal Size Reduction in Planarians through Successive Regenerations," S. J. Holmes.

"Studies in Fertilization in *Nereis*." 1. "The Cortical Changes in the Egg." 2. "Partial Fertilization," F. R. Lillie.

"The Physiology of Cell division." 4. "The Action of Pure and Calcium containing Salt-solutions, followed by Hypertonic Sea water, on the Unfertilized Eggs of *Arbacia*, with a Theory of the Physics of Certain Features of Mitosis from the Standpoint of the Membrane Theory of Bioelectric Processes," Ralph S. Lillie.

"Anatomical Illustrations before Vesalius," W. A. Locy.

"The Growth and Retrogression of *Corpus luteum* in the Guinea pig," Leo Loeb.

"The Chemistry of Fertilization," A. P. Mathews.

"The Influence of Inbreeding and Selection on the Fertility and Sex Ratio in *Drosophila*," W. J. Moenkhaus.

"The Spermatogenesis of the *Hempteron Euschistus*," T. H. Montgomery, Jr.

"Further Studies of Ovogenesis and Spermatogenesis in Phylloxerans and Aphids," T. H. Morgan.

Studies of Variation and Heredity in the Armadillo," H. H. Newman and J. T. Patterson.

"Foot Movements of Molluscs," G. H. Parker.

"The Evolution of the Pearl Organs of American Minnows and Suckers. A Study in the Factors of Descent," Jacob Reighard.

"White and Yellow Yolk in Vertebrate Ova," Oscar Riddle.

"The Structure and Periodicity of the Developing Salpa Chain," W. E. Ritter (With Miss Myrtle Johnson).

"Physiological Animal Geography," V. E. Shelford.

"The Olfactory Organs and the Sense of Smell in Birds," R. M. Strong.

"The Behavior of the Chromosomes in Cross-fertilized Echinoid Eggs," D. H. Tennent.

"Experimental Modification of the Germplasm," W. L. Tower.

"The Ant colony as an Organism," W. M. Wheeler.

"Studies in Chromosomes." 7. "A Review of the Chromosomes of *Nezara* with some more General Considerations,' E. B. Wilson.

"*Paramæcium caudatum* and *Paramæcium aurelia*," L. L. Woodruff.

"Experiments in the Control of Asymmetry in the Development of the Serpulid, *Hydroides dianthus*," Charles Zeleny.

Titles of papers of the following not received: H. McE. Knower, Jacques Loeb, F. P. Mall.

SCIENTIFIC NOTES AND NEWS

THE congress has passed a bill to retire Commander Robert E. Peary, with the rank and pay of a rear-admiral and to extend to him the thanks of congress.

THE vacancy in the board of consulting scientific experts to the secretary of agriculture, caused by the death of Dr. C. A. Herter, has been filled by the appointment of Dr. Theobald Smith, of Harvard University. The appointment was made by the secretary of agriculture, with the full approval of President Taft.

THE Helmholtz medal of the Berlin Academy of Sciences was awarded to Professor van't Hoff shortly before his death.

SIR WILLIAM H. WHITE has been awarded the John Fritz medal for 1911, for "notable achievements in naval architecture," by the board representing the national societies of civil, mining, mechanical and electrical engineering. The first award was made in 1905 to Lord Kelvin, and subsequently to Alexander Graham Bell, Thomas A. Edison, George Westinghouse, Charles Porter and Alfred Noble.

THE gold medal of the British Institution

of Mining and Metallurgy has been awarded to Sir Julius Wernher, in recognition of his services to technological education and in the promotion of the interests of the mining and metallurgical professions.

Dr. L A Bauer was made an honorary member of the Royal Cornwall Polytechnic Society of England at its recent annual general meeting

The Academy of Natural Sciences of Philadelphia has elected Dr Walter Rothschild, of Tring, England, a correspondent

Professor Bier, director of the surgical clinic at Berlin, has been elected a foreign member of the Berlin Academy of Sciences

Mr Norman Taylor, editor of *Torreya*, and assistant curator at the New York Botanical Garden, has been appointed curator of plants in the newly established Brooklyn botanic garden

Dr Clarence J Marshall, professor of veterinary medicine at the University of Pennsylvania, has been appointed veterinarian of the state of Pennsylvania

David Albert Molitor, professor of topographic and geodetic engineering in the College of Civil Engineering of Cornell University, has resigned from the faculty and returned to active practise

Dr Henry C. Taylor, professor of agricultural economics at the University of Wisconsin, has been elected associate editor of *The American Economic Review*, published by the American Economic Association Dr Taylor will have charge of the subject of agricultural economics

Dr Alice Hamilton, of the Memorial Institute for Infectious Diseases, of Chicago, who investigated the lead industries of Chicago and Illinois with reference to lead poisoning for the Illinois Commission on Occupational Diseases, is undertaking similar work for the federal government

The Frederick Sheldon traveling fellowship of Harvard University has been awarded to Latham Clarke, Ph D, instructor in industrial chemistry

Professor Giuseppe Mercalli has been appointed director of the observatory on Mt Vesuvius, to succeed Professor Matteucci

Professor E B Wilson lectured on "Heredity and the Cell" before the Society of Sigma Xi of Columbia University on February 23

Dr L H Bailey, director of the New York State College of Agriculture at Cornell University, delivered a lecture under the auspices of the Pennsylvania Chapter of the Society of the Sigma Xi on February 27, on the subject of "The Country Life Situation"

Two Sigma Xi lectures, one on "Attention" and one on "Types of Mind," were given at the University of Minnesota, on February 9 and 10, by Professor E B Titchener, Sage research professor at Cornell University.

The Columbia chapter of the Phi Lambda Upsilon, the honorary chemical fraternity, was addressed by Dr H W Wiley, of Washington, D C, on February 18 In his address on the "Relation of Chemistry to the Public Welfare" Dr Wiley showed the moral influence which a chemist exerts on the community and the position which a chemist will assume in the fight against disease An informal reception to Dr Wiley was tendered by the society after the address to welcome him as a member

The annual meeting of the Illinois State Academy of Science was held at the University of Chicago on February 17 and 18 Professor J M Coulter, head of the department of botany of the university, delivered the presidential address on "The Problems of Plant Breeding"

On January 21 the Oregon Academy of Sciences met in regular monthly meeting, the address being by W. N. Ferrins, president of Pacific University and one of the Rhodes scholarship committee for the northwest His subject was "The Rhodes Scholarships and Oxford University" On February 18 Wm T Foster, president of the new Reed College, of Portland, spoke on "The American College," giving a brief review of the history of European colleges At the March meeting Pro-

fessor Albert Sweetser, biologist of the University of Oregon, will deliver an address.

THE Society of College Teachers of Education held its convention during the sessions of the Department of Superintendence of the National Education Association on February 23 and 24 in Mobile, Ala. The president of the society was Charles H. Judd, professor of education in the University of Chicago.

PROFESSOR ARTHUR KEITH, conservator of the museum of the Royal College of Surgeons of England, gave in February a course of six Hunterian lectures on the fossil remains of man, and their bearing on the origin of modern British types.

AFTER the scientific program, at the session of the Philadelphia College of Physicians, on February 1, Dr. Robert Abbe, New York City, presented to the college the gold watch of Benjamin Rush, and Dr. William W. Keen, on behalf of the donors, presented to the college a portrait of Dr. William Goodell, the gynecologist.

BY the instructions of the London County Council, as we learn from *Nature*, a blue tablet of encaustic ware has been affixed to No. 32 Soho Square, W., at one time the residence of Sir Joseph Banks, who was elected president of the Royal Society in 1778 and held that office for forty-one years.

SIR JOHN MURRAY will give his memorial address on "The Life and Scientific Works of Alexander Agassiz," at Sanders Theater, Harvard University, on Wednesday evening, March 22, at eight o'clock. On account of Sir John Murray's illness this lecture was postponed from February 14.

DR. WALTER REMSEN BRINCKERHOFF, assistant professor of pathology in the Harvard Medical School, the author of important researches on small-pox and leprosy, died in Boston, on the second of March, in the thirty-seventh year of his age.

THE death is announced from Berlin of Professor J. H. van't Hoff, eminent for his contributions to physical chemistry.

DR. ALOYSIUS OLIVER JOSEPH KELLY, assistant professor of medicine in the University of Pennsylvania and professor of pathology in the Woman's Medical College of Pennsylvania, died on February 23, at the age of forty-one years.

THE second Central American Expedition of the School of American Archeology reached Guatemala on January 14 and steps were immediately taken to continue the work inaugurated the preceding year. After a preliminary survey of the southern Maya field year (January, 1910), it was decided that the School of American Archeology would undertake the excavation and repair of the ruins of Quirigua in the Department of Izabal, some fifty miles from the Atlantic coast. During the first expedition the ruins were surveyed, and a park laid out surrounding them. The Great Plaza was cleared of underbrush and the monuments were cleaned, photographed and measured. A first hand study of the art and inscriptions was undertaken and in both cases the inadequacy of photographs and casts for definitive conclusions was demonstrated. The second expedition will continue the work from this point. The luxuriant tropical vegetation in which the ruins lie buried will be felled and means taken to prevent the annual reappearance of this destructive agent. The laying bare of this site, the clearing of the various pyramids, courts and temples will doubtless be the main work of the present season, though excavations will also be made and the study of the art and inscriptions continued.

THE Lake Laboratory of the Ohio State University has announced its courses for the summer session of 1911, and covers practically the same ground as in previous seasons. The staff includes representatives from a number of Ohio Colleges, including Professors Brookner, of Buchtel, Coghill, of Denison, Fullmer, of Baldwin; Osborn and Landacre, of Ohio State University, and Jennings, of the Carnegie Museum in Pittsburgh, with one position, in ornithology, yet to be filled. The subjects covered are general zoology, aquatic biology, invertebrate zoology, entomology,

ornithology, experimental zoology, embryology, general botany and ecology, each in charge of a specialist in the subject The opportunities of work in these lines are very favorable, the laboratory being located on Cedar Point with access to Lake Erie, on the one side, and Sandusky Bay, with its marshes and open water, on the other side It is also quite near the islands and to all points of zoological interest The session opens on June 19, and further information concerning the work or copies of the announcement may be obtained by application to the director, Professor Herbert Osborn, Ohio State University, Columbus, Ohio.

A BIOLOGICAL club has been organized at the Oregon Agricultural College by the faculty and graduate students to make studies of the biology of the state Professor H S Jackson, of the department of botany, was made chairman for the coming year with George F. Sykes, of the department of zoology, as secretary. The club voted to make one of its first problems a thorough biological survey of Mary's Peak, a work which will occupy at least two years Through the meetings, field trips and collection of material, it is hoped to add materially to the present knowledge of the biology of the state, while at the same time interest will be stimulated in the study of biology

THE sixty-third meeting of the American Society of Mechanical Engineers will be held in Pittsburgh, Pa, from May 30 to June 2, inclusive. The society has not met in this city since 1884. The headquarters of the society are in New York City, and Col E D. Meier, of St Louis, is president this year The society has in the Pittsburgh district alone a membership of about one hundred and sixty. Last year the society held a joint meeting in England with the British Society, the Institution of Mechanical Engineers An executive committee consisting of E M. Herr, chairman, George Mesta, J. M Tate, Jr, Chester B. Albree, D. F. Crawford, Morris Knowles and Elmer K Hiles, secretary, will have charge of the Pittsburgh meetings. There will be professional sessions when papers will be read and discussed There will also be inspection trips through the leading local industrial establishments

THE progress of the graduate electrical engineering work at the Massachusetts Institute of Technology is indicated by the number of students who are candidates for higher degrees, which number is now greater than last year. The number of students in the undergraduate course in electrical engineering is also steadily increasing so that additional teaching staff is being added to the corps of laboratory instruction Various lines of research are being carried on in the department mostly under the direction of Professor Pender and Professor Wickenden Some of these relate to the effects of heat treatment on the magnetic qualities of silicon iron, certain transient phenomena that may occur in long electric circuits, the effect of high frequencies on the permeability of iron, the effective resistance and reactance of steel rails when conveying alternating currents, the selective action of spark gap lightning arresters with respect to frequency, the reflection of light from walls and ceilings, the disruptive strength of rubber insulated coatings, on wires, etc. Certain of these are continuations of work started last year, and researches in each will be carried on as may be convenient and needful to get knowledge of the phenomena under investigation The results of the thesis research of Dr Harold Osborne on whom the degree of doctor of engineering (the first conferred by the institute) was conferred last June, were embodied in a paper presented before the American Institute of Electrical Engineers at its October meeting The subject of illumination and photometry has been added to the subjects taught in the electrical engineering department This is treated from the standpoint of what is generally called illuminating engineering and is made an optional study

IT is reported that the Italian government will establish a Vulcanological Institute, for which the chief governments will be invited to contribute £60,000. Mr. Immanuel Friedlaender, who resides in Naples and is the author of a work on the volcanoes of Japan, has promised, it is said, £4,000 towards this fund

THE second Shaler Memorial Research, supported by the Shaler Memorial Fund of Harvard University, will consist of a study of shoreline changes along the Atlantic coast by Professor D. W. Johnson and two or three assistants. Special attention will be given to changes in the form of beaches within recent geological time, and to supposed evidences of recent coastal subsidence. Since the problem of coastal subsidence is affected by the relative heights of high tides on the outer and inner sides of barrier beaches, lines of levels will be run between the ocean and lagoons, upon which tidal observations will be based. The most important localities from the Bay of Fundy to southern Florida will be examined during the spring and early summer. During the latter part of the summer Professor Johnson will visit localities on the coasts of England, Holland and Sweden, for the purpose of making comparisons with similar localities on the Atlantic coast of North America.

UNIVERSITY AND EDUCATIONAL NEWS

M. AUGUSTE LOUTREFIL has bequeathed $700,000 to the Paris Academy of Sciences, $500,000 to the University of Paris and $20,000 to the Pasteur Institute.

THE University of Michigan has received a gift of $10,000 from William J. Cook, now of New York, and formerly of Hillsdale, Mich., to be used toward the erection of a residential hall for women.

BY the will of Miss Susan G. Lansing, of Albany, N. Y., Rutgers College receives the sum of $5,000, together with one third of the residuary estate, which, it is estimated, will bring about $10,000 additional.

THE residue under Sir Francis Galton's will is bequeathed to the University of London for the encouragement of the study of eugenics.

THE technique of printing and publishing is a new course of study at the University of Wisconsin in connection with the course in journalism. It is designed for students of agriculture, engineering and commerce, who are preparing to enter technical and trade journalism. A class in technical and trade journalism has been organized to give further training in this field.

THE University of Illinois special train to rural schools started out for a two weeks' trip over the Illinois Traction system on February 27. The special consists of two cars fitted up with illustrative material for the use of the speakers who accompany the train. About one thousand children are visiting this special every day. The county superintendent of schools of each county that the special visits accompanies the party and acts as guide and director.

PROFESSOR V. H. BLACKMAN, of Leeds, has been appointed to the professorship of plant physiology and pathology at the Imperial College of Science and Technology, London.

DISCUSSION AND CORRESPONDENCE

THE USE OF NUMERALS FOR SPECIFIC NAMES IN SYSTEMATIC ZOOLOGY

IN a recent number of SCIENCE, Dr. Needham has suggested the use of a numerical system of naming species, in addition to the present binomial system devised by Linnæus.

To this suggestion there are several objections, which to the practical worker in taxonomy seem wholly insuperable. In the first place, the name of an animal is not the main element concerned. The specific name covers our conception of the species, a conception likely to be greatly modified by thorough study. The generic name indicates our conception of where it belongs. This conception, of necessity, changes with the progress of knowledge. The changes in name mark such progress. To the taxonomist, certain changes of name are as real and as important as any other forward step in science. It is of course unfortunate that some species have had many different names. So have many genera also. This is due primarily to the inherent difficulties of the subject, as few branches of knowledge are more intricate than the study of the genetic derivation of forms, and their exact geographical distribution. These two branches of science, taxonomy and zoogeography, must

depend for their existence on exactness in nomenclature. Besides this, it often happens that a publication in one nation may be unknown in another, that different writers reach the same results almost simultaneously and independently, and still worse, that some writers are careless or ignorant of the literature, or have felt free to improve on the work of their predecessors by changing, not their conceptions, but the names they have given.

This condition in which anybody called any animal or plant what he pleased went on for more than eighty years after the publication of the "Systema Naturæ." It was evident that all exactness in nomenclature was being lost and that the only way out was through the law of priority and through considering systematic zoology as a democracy in which there was no respecting of persons. Since the first attempt at the recognition of the law of priority in nomenclature, we have come by degrees to relative stability. So far as the first name given to species or a genus was concerned, this name, unless already in use, is right. All the others are wrong. To those who regard rules, the number of names doubtful from the standpoint of nomenclature is now but a very small proportion of the total number. Those zoologically doubtful are naturally far more numerous.

The many zoological problems involved must be settled by observation of the facts in nature, not by rule. There is scarcely a species of which we finally and completely know the actual boundaries. The value and limitation of generic groups changes with every increase of knowledge. Forms once placed side by side are shown to belong far apart. Those far apart are often brought together. In this regard, there can be no stability until the facts are all in. A nomenclature absolutely stable would represent intellectual stagnation.

But to the systematic worker in any field, the actual changes bring no great inconvenience. Names are nothing without ideas. His difficulties do not lie in the remembering of names, but in getting the facts to which names are the handles. The postman is not worried over the fact that each town has a name, and that it belongs to some county, and that there are many counties in many states. If he has troubles, it is not because there are so many names, but because there are so many towns and so many people to be named. So with the taxonomist in any field.

To the worker in other lines in biology, who asks of taxonomy nothing save the name of the animal he is working on, all suspense is aggravating. He wants the scientific name once for all, and he doesn't want it changed. We are sorry that we can not accommodate him, but a name as such is not the main question with the taxonomist. We may let the anatomist keep for his own purposes such names as *Amphioxus*, although the taxonomist can not use it, because the group had a name before *Amphioxus* was invented. The anatomist may in time get used to *Branchiostoma* just as he has become reconciled to *Necturus*, in place of the much later *Menobranchus* once sacred to his purposes.

The fact that a name seems to be in common use just now is no argument for its permanence. The next generation realizing more and more the value of law and order, will discard the name that should not legitimately be used. It is just as necessary in taxonomy and in zoogeography to have a clear-cut nomenclature—above all whim or personal preference—as it is in anatomy to have clean knives, or in histology to have trustworthy staining fluids.

As to the substitution of numbers for specific names or their use in place of such names, we have first the minor objection, of inaccuracy. There will be a dozen errors in a column of figures to one in a column of names, because with the numerals the memory has nothing to hold to. If you live at No. 163 West 135th St. half your letters will be misdirected. This can be easily tested. The dead-letter office is sending back to me letters I directed to 916 East 19th St., and to 919 East 14th St., which should have gone to 914 East 19th, and I have now to write those figures twice to be sure that they are right. No. 256 Knickerbocker Avenue does not have this trouble. Besides, misprints in names correct

themselves Slips in numbers can not do so.

But waiving all this, the plan seems utopian Let us look at its application to the group of fishes There are about 12,500 known species of fishes, arranged in about 2,500 genera Over 4,000 genera have been named and upwards of 30,000 to 40,000 species Of these names, perhaps 10,000 are known to be synonyms, the result of some one's misfortune or carelessness The majority of the supposed species have not been tested The seas are large, there are many rivers, and but few men who study these animals thoroughly In our system of numbers shall we count real species or merely count names? Manifestly it is only the names which we can use, for we do not know half the species well enough to assign them a final place Again, shall we number all species of fishes from 1 to 40,000—or shall we number them by groups or by genera? In any case, a single man or bureau must do all the numbering for all the world, else we should have a crossing of numbers. I might use 38,927 for my cat-fish, while my Russian friend might claim it for a sturgeon If we number by genera, my *Ameiurus* 36 may not be the same as my friend's *Ameiurus* 36 issued at about the same time Or one or the other might make an error, or misprint, duplicating what is already numbered

We must then have in each group a central numbering bureau, a bureau which shall have the means to go back and number all the forgotten species already in literature We would have to do this before the work could begin Our American channel cat, *Ictalurus punctatus*, has received some 27 specific names after it was called *Silurus punctatus*. To do it justice, we must refer to it as *Ictalurus*, 5, 27, 36, 38, etc., thus including the whole list of synonyms, any one of which some one some time may show to be valid. But the channel cat was not originally called *Ictalurus*. This raises the question as to whether you would list it as *Silurus*, which it is not, or as *Ictalurus*, which it is, or as *Ameiurus*, *Elliops*, *Synechoglanis*, *Pimelodus* or other generic names under which synonyms its species have been recorded.

Manifestly they must be listed under the original generic name, for no one yet knows the final boundaries of the modern genus. The modern genus consists of a group of species clustering round its original type The boundaries between *Ictalurus*, the channel cat, and *Ameiurus*, the ordinary cat fish, are still uncertain There are species intermediate, with the head of *Ameiurus* and the tail of *Ictalurus*, and it may be that the two must coalesce So the same channel cat may be *Silurus* 25, *Ameiurus* 29, *Pimelodus* 75, *Synechoglanis* 1. Under the law of priority, it can have but one right name This is *punctatus*, the oldest specific name attached to its right genus, which, as we now understand it, is *Ictalurus*

But let us start the numbering and see where we come out Shall we begin with the lowest fish or with the fish first made known? Our system of nomenclature begins on January 1, 1758 The first fish named is the common lamprey, *Petromyzon marinus* *Petromyzon* offers no difficulty, except that according to Linnæus, *Petromyzon* is not a fish, but an amphibian His *Amphibia nantes*, or swimming amphibians, in his mind are not real fishes

Passing on to the first species actually called a fish by Linnæus, *Muræna helena*, the European moray, we have then *Muræna* 1. But this Linnæus *helena* obviously is not a species It is a compound of what is now called *Muræna helena*, identifiable from its use at the suppers in honor of Helen in Rome, to which Linnæus refers, and of two other species, one of the old world, one American. *Muræna* 1, therefore includes *Muræna* 50 (—*Gymnothorax moringa*) and *Muræna* 90 (*polyzonia*). But we will use the name *helena* for the Roman moray *Muræna* *Muræna* 2 (*ophis*) is—no one can tell what—a species of *Ophichthus*, and *Muræna* 3 (*serpens*) is the type of the later genus called *Ophisurus* or *Oxystomus* It has very little in common with the morays. Have we gained much by substituting *Muræna* 1, *Muræna* 2 and *Muræna* 3, for *Muræna helena*, *Ophichthus ophis* and *Ophisurus serpens*?

But perhaps it will be best to begin at the bottom of the series The lancelet is the lowest fish, if (1) it is a fish, and (2) if the *Tunicates*, and the *Balanoglossi* are not also fishes If we number the fishes from 1 to 40,000, we shall have to decide beforehand as to the nature of tunicates, lancelets, lampreys, chimæras and sharks as well as that of their various extinct relatives. Apparently the only safe way will be to number the species after another, each in the genus in which it was originally placed In that case, the genus may go where it will, the species will hold their numbers.

In 1774, Pallas named the lancelet, *Limax lanceolatus*. But it is not a *Limax* *Limax* is a land-slug Must we wait till other shell-less snails or *Limax* are numbered, before we can list our first fish Let us chance it as *Limax* 75 and keep it with the fishes if we can

In 1834, Costa named this same lancelet *Branchiostoma lubricum* *Branchiostoma* 1 is therefore equivalent to *Limax* 75 But the species should not be called *lubricum*, but *lanceolatum* This Yarrell recognized in 1836, calling it *Amphioxus lanceolatus*, bringing up the old specific name But his generic name, new and useless, has been the source of much subsequent trouble In any case the species is not *Amphioxus* 1, because it does not start with *Amphioxus*. It was known sixty years before the time of Yarrell

Our next fish is *Branchiostoma caribæum* of Sundevall in 1853 This is a doubtful species, most likely the same as *B lanceolatum*, but it may stand as *Branchiostoma* 2 *Branchiostoma Californiense* Gill 1898 may be *Branchiostoma* 3, and the remaining lancelets are scattered over the world, some recorded as *Amphioxus*, most as *Branchiostoma*

It is not necessary to follow this further. The same conditions prevail throughout zoology The fact is that our present Linnæan system of naming species and groups in zoology or botany is still the best which has been devised or suggested It has the right of way through one hundred and fifty years of usage. All present taxonomy is based upon it. Its embarrassments are due chiefly to the difficulties inherent in the subject, and to the limitations of human nature.

The changes in names of the last thirty years have been, on the whole, in the direction of final stability. The zoologists of the world have devised machinery which will steadily make for permanence, and the necessary period of transition is one from lawlessness to law, from confusion to science In so far as we have confusion this has arisen through neglect or ignorance of law. It can not be remedied by further neglect A writer dealing with scientific names must either call an animal or plant whatever he pleases, or else he must conform to regulations inherent in the nature of his work Arbitrary rules will soon be disregarded The necessary regulations are those which future workers will approve, and we, who are still working in the infancy of taxonomy, must lay foundations on which the future can build

In view of the great issues which depend on accuracy of method, such minor issues as that we rather say *Amphioxus* than *Branchiostoma*, or that it suits us better to call the common eel *Anguilla vulgaris* rather than *Anguilla anguilla*, or that our collection is labeled according to the method of Cuvier, sink into insignificance You can say *Amphioxus* if you like—or *Bdellostoma* We shall know what you mean, but we shall not try to force these names back into nomenclature, replacing older and legitimate names already becoming better known to the actual worker in taxonomy than these names of temporary convenience ever were or ever will be

DAVID STARR JORDAN
STANFORD UNIVERSITY

THE USE OF SYMBOLS IN ZOOLOGICAL NOMENCLATURE

AT first thought, Dr Needham's suggestion[1] that in substance we designate what are practically subgenera, species and so on, by symbols does give more or less of a shock Never-

[1] SCIENCE, N S., XXXII, pp 295–300, September 2, 1910, see also *ib*, pp 428–429, September 30, 1910, and XXXIII, pp 25–29, January 6, 1911

theless, a little thought certainly shows that some such system as this may be a necessity in the near future and, if for no other reason, should receive earnest attention and discussion The system proposed by Dr Needham has obvious advantages By grouping closely related genera (becoming subgenera) under the old name of the genus when used in its widest sense, two of the fundamental reasons for the existence of nomenclature are reached, namely, stability and ease in identification and in grasping the relations of the various units at a glance But, to my mind, the system has nothing at all to do with stability unless this fundamental change is instituted All will grant, I think, that stability is fundamental, as is also ease or at least possibility of identification I believe, too, that all will concede that neither is possible without what may be called "rigidly" defined genera (=groups), genera which all are willing to rank as such and which all will be able to recognize (perhaps they would be equal to present-day subfamilies at least)

These genera or groups being firmly established by universal acceptance and concise description, then the application of the symbols would doubtless save an immense amount of space Otherwise, I am certainly at a loss to find any other advantages which they may have Synonymy nor anything else is simplified by saying that $5 = 4$ instead of *leucopsallis* = *viridis* The only thing that matters is whether the statement is true or not. You may call 5 anything that you wish without changing what it represents And is it not true that most of our troubles cluster about the fact that we have been unable to find out what authors have meant to represent?

The objections to involved nomenclature entered by the zoologist and biologist are entitled to much consideration, but we should not lose sight of the fact that the present systematic unit—the species—was founded by themselves and seemingly we still find an endless number of them If it is true that they exist it is our duty to keep on recording them. Whether we call them by symbols or names isn't to the point at all. The gist of the matter is, shall the conception of the systematic unit be changed from "natural" species to conceived genera? Will any biologist deny that species exist Why, therefore, should they wish to escape from them? It is true it is impossible to know all of them nor even their names! But who wants to do this The fact that they exist is true, or else our conception, or rather perception, of a species is all wrong Now, if it is true that they exist, I believe that it is necessary that they be represented by names or else symbols. Thus, whether names or symbols are used, either would have to be used an equal number of times, but the symbols would be shorter, that is all It is not the jungle of names that masters us, is it? Rather, is it not the jungle of things? To simplify, natural laws, not symbols, are needed

Therefore, it seems to me that the fundamental plan suggested by Dr Needham, that of falling back upon the old genera and their names, is the only way out of the confusion, present and past As for the symbols, they are preferable only in so far as they have a tendency to simplify, not our knowledge, which they are certainly unable to do here, but our working methods, time and space.

A ARSÈNE GIRAULT

URBANA, ILL,
January 9, 1911

ON FACTORS CONTRIBUTING TO A LOW SCIENTIFIC PRODUCTIVITY IN AMERICA

A FEW months ago I offered some criticisms on a paper by Professor Gunn which appeared in SCIENCE for October 28, 1910, under the caption, "American Educational Defects." My criticisms were directed chiefly to the method adopted by Professor Gunn, and he has very properly retorted[1] that I should not make too much of the matter of method unless I am prepared to dissent from the practical outcome of his study.

Now so far as this outcome was to the effect that the level of scientific and scholarly productivity in this country is unsatisfactory by comparison with that in certain European

[1] SCIENCE, January 20, 1911, N S, XXXIII, 107

countries, I am not prepared to dissent I do indeed believe that Professor Gunn's picture is overdrawn, when he describes our achievements in pure science as "insignificant," for it is easy to point to achievements of very high grade, even in such branches as mathematical physics and philosophy, while of recent years there has appeared a considerable volume of quite respectable work Still, I should admit that the work of very high quality has been too small in amount, and that the volume of recent work suffers somewhat in an appraisal of its quality I should indeed be inclined to make a further reservation on this last point, as far as my own acquaintance with scientific literature goes, for in my own field of experimental psychology, which has hitherto been chiefly cultivated in Germany and in America, I am unable to detect any pronounced superiority of the German work. The Germans do, certainly, manage to give their contributions a more important sound, their articles are more extended, and run out almost indefinitely into discussion and theoretical considerations, but much of this is of little real value, and many an American paper of modest length contains as much of real contribution to knowledge as does its German analogue of a hundred or two hundred pages However, let us freely admit that, when we consider the number of men here who might be expected, from their training and their positions, to be scientific producers, we find the total productivity surprisingly small. There is much to indicate that this is the fact: so numerous are the cases of young men who have produced a creditable doctor's dissertation and obtained a college position in their specialty, but from whom nothing further is heard in the way of original contribution, and so numerous also are the cases of men of proved ability, who, after a few years of activity and after winning a professorship of dignity, allow their output to cease Good minds and good opportunities appear to be going to waste, and the problem of the causes of this condition is one of the highest importance to those who are interested in the advancement of science. It is a problem which deserves treatment by the most painstaking methods of science, unfortunately, I can make no great claims for my own method, for I have by no means conducted researches on the large scale demanded by the complexity of the problem I have, however, for a considerable number of years been keenly interested in this particular problem, and am prepared to adduce a certain number of facts, which, as facts, will scarcely be called in question, and which I shall try to show are probably pertinent

I will first adduce my list of facts, in summary form

1 The economic rewards for scientific production, and punishments for lack of it, have been smaller here than elsewhere

2 Similarly with other social rewards and punishments

3 The rapid expansion of our educational system has created a demand which has absorbed the whole supply of even reasonably qualified men

4 This educational expansion has been but a feature of the general national expansion, and the general demand for men of ability has operated still further to reduce the keenness of academic competition, and so to lower the standard of academic success

5 This rapid expansion, in the presence of our decentralized form of governmental control and generally fluid condition, has made the business of the educational and scientific promoter one of great importance, has operated to give the greatest economic and social prizes to the promoter, and has caused scientific men to spend their time running errands in the interest of science rather than prosecuting their individual research

6 The educational interest, as distinguished from the strictly scientific, has been strong among us, and has led to a considerable deflection of effort from the work of science[3]

[3] There is another probable fact, which I do not include in the list because I am not sure of it, and because it could be determined by suitable inquiry, in advance of which it is best not to guess at the fact The probability is that our young men do not begin to specialize so early as their scientific brethren in Europe, and if this is

Lest I should be accused of altogether neglecting principles in my zeal for facts, I will also mention a few general principles which can properly be employed in reasoning from the above facts

1 The law of supply and demand.

2 The law of the value, as incentives, of rewards and punishments

3 The law of divided energy, according to which a man can not do so much in a given line if his time and energy are largely devoted to something else.

The great fact of rapid expansion is perhaps the most important of all. Since the most obvious feature of this expansion has been that of the economic development of the country and of the growth of industries, the fact is usually hit off as commercial expansion, and the effort made to deduce all our peculiarities and deficiencies from our commercialism But the real fact is expansion, a fact, it is probably of great importance. Our own delay in getting the young man fairly launched on his scientific career is partly due to our superstition that the traditional four years of college marks a minimum of time to be devoted to "general culture," after which, only, should specialization begin Meanwhile, through the raising of the standards for admission to college, the period of specialization has been deferred to about the age of 22 But besides this, it often happens that a man just leaving college and bent on a scholarly career is led to believe that the best step for him next to take is to teach in a secondary school, and thus the age at which he enters on really advanced study is likely to be delayed to 25 From observation of men studying for their doctor's degree, I am convinced that the man who goes straight on from college to the university is usually the one who comes off best in his graduate study The years immediately following the age of 20 are of great value for the ready assimilation of knowledge, and, moreover, the most original period of a man's life is likely to follow close upon these years, and unless he has good command of his specialty by the age of 25 or 27, he is rather unlikely ever to have many original ideas on the subject I am convinced that specialization, for any young man whose bent towards a scholarly pursuit is sufficiently marked to warrant urging him to undertake it, should not be delayed much beyond the age of 20 not commercialism—expansion in all directions A necessary result of this expansion, and a result abundantly in evidence, is that the demand for labor of all kinds, and not least for the labor of intellectually able men, has been great in relation to the supply. The economic reward for intellectual ability has, of course, been much greater in many other lines of work than in the academic, and this has certainly further limited the supply available for scientific pursuits. For example, it has been, and is, difficult to man the laboratory departments of our medical schools, for the reason that the rewards awaiting the successful physician, in practise, have been far in excess of anything he could hope for in research The financial reward for scientific work is everywhere less than the reward for equal accomplishment in other lines; but here this difference is accentuated. In spite of this fact, scholarly pursuits continue to attract a very considerable number of really able men. The men are attracted in part by the freedom of the academic life, in part by the undoubted prestige attaching to good academic positions, and in largest measure, no doubt, by the work itself Improvement of the general economic status of university and college teachers is of course greatly to be desired in the interests of broadening the labor market for this highly important sort of work, but that is by no means the key to the whole situation, for we are confronted with an able body of men, men who have proved, in many cases, their ability in original work, but who nevertheless leave much to be desired in the way of productivity

The expansion of our educational system has, if anything, outstripped our commercial expansion Universities have multiplied and grown enormously, teaching forces have been greatly augmented, and the demand for high-class men to fill academic positions has been ever on the increase The demand has been large in proportion to the supply, so that every moderately equipped candidate has been assured of a post of some dignity. Promotion has been rapid, as far as it goes. In other words, the labor market for all grades of academic work has been relatively narrow, and

there has been an absence of keen competition either for the lower or for the higher positions This is a necessary result of expansion, and, at any rate, it is a fact The conditions, as regards competition, are very different in some European countries A young man there must often serve a long apprenticeship in a very poorly paid position, and can only rise out of this difficult situation by overcoming keen competition Our rather tame discussions of the work of our colleagues lack the keen note of economic competition which is often heard in European controversy Here, we feel, there is room enough for all, and on an approximate equality. Here it makes comparatively little difference to a man, economically, whether his scientific work is mediocre or of eminent success For while the ratio of demand to supply assures him of at least a moderately good position, there is nothing in the way of a very fine position to spur him forward While mediocre men are better off here than in several other countries, very good men, in purely academic positions, are by no means so well off as elsewhere. In Great Britain, at least, there is a considerable number of professorships the financial value of which, when allowance is made for the different purchasing power of money, is fully the equivalent of eight to twelve thousand dollars The financial value of these posts is well known throughout the kingdom, and, as they are permanent establishments, and are filled, when they fall vacant, in the open market, they act as a very effective stimulus to productivity They act as a stimulus to a class of men whom it is most of all important to stimulate, and who, in our country, are subject to no such incentive—namely, to the men of greatest ability, who have already proved their power and have already achieved positions as good as any we have here to offer. Not only a high money value, but also great prestige, attaches to some of these chairs, because of the eminent men who have occupied them in the past. We have practically nothing to correspond to them; and this is, I believe, one of the great deficiencies of our system Nowhere, it would seem, is the punishment for idleness so light as in our academic life, and nowhere is the reward of productive industry so meager I am far from contending that the mere financial reward is the sole stimulus to scientific production, but these prizes not only bring great financial relief, they are also the seal of success I might paraphrase what I said a few sentences back by asserting that nowhere is there such a lack, as in our American academic life, of the tangible symbols of success and failure in scholarly work

To punish mediocrity is scarcely within our power during a period of rapid expansion, but to reward proved merit is in our power Why should not a university, numbering among its professors some one of the acknowledged leaders in American productive scholarship, simply double or triple his salary, at the same time doing all it can to strengthen his department, and thus secure to itself preeminence in that particular subject among all our universities, insuring, further, a continued preeminence by permanently establishing this distinguished chair and this thoroughly equipped department? It should be possible in this way for a university to attract a large share of the best graduate students in this department, and thus add further to the influence of the chief and to the attractiveness of his position. The combined prestige, influence and financial desirability of such a position would make it a prize for the competition of the ablest of the younger men. There is no reason why such prizes should not act as effective spurs here as elsewhere. Our effort has been devoted more to raising the general level of compensation and attractiveness of all professorial positions than to the recognition of eminent scholarly and scientific success. Certainly there is abundant need for raising the general level of salaries to keep pace with the changing ratio between money and other commodities. But the reward of eminent merit is a thing apart

Another consequence of rapid expansion, under the decentralized and rather unorganized conditions of our national activity, in which such an interest as the educational must look out for itself, has been the evolution of

the organizer, agent and promoter. The most striking instance is the university president or chancellor. His function has been distinctly that of the promoter, and so important has this function appeared in a period of expansion that the largest rewards, both pecuniary and in the way of social standing and influence, have gone to the presidency, and some of the ablest and most efficient from the professorial ranks have been drafted into administration. Since the duties of the president have been too exacting to allow a continuance of scholarly work, the result has no doubt been a considerable shrinkage in the volume of possible production. Further, ambitious young professors, observing which way the path of distinction led, have often set themselves to prove their ability in administration rather than in scientific production. Administrative opportunity has abounded throughout the educational system, and many who entered the system from love of science or literature have found their attention largely absorbed by matters of management and promotion. Much of this bustling administrative activity has been a necessary result of expansion, but much of it has been due to mere contagion and mutual emulation. The center of competitive activity has been shifted from scholarship to administration. Now all administrative work, however necessary in the circumstances and however ably performed, is but a means to the ends of scholarship and of education, and it seems a pity that so much of the best brains should go to the means and so little be applied directly to the ends in view. The head of a department, instead of entering his laboratory with the thought of his experiment uppermost in his mind, is first of all oppressed by the condition of his desk. When that is cleared up, he hopes to go ahead with his investigation, but the desk occupies him for so large a part of the day that the experiment is deferred till to-morrow. There is a tremendous dissipation of energy among university professors. We are always busy, but seldom get down to business. We are always busy trying to insure that the work of science be done, and leave little time to do the work ourselves. We are so much occupied in contributing to the advancement of science that we are unable to make contributions to science.

The attention of our scholars has been deflected by educational as well as administrative interests. I am inclined to regard this, too, as a consequence of expansion. For our higher institutions of learning have expanded in faster ratio than the general population, and this means that we are undertaking to educate many who are not specially suited to a higher education. Since the net has been made finer, we are catching many small fish, and the educational problem is largely concerned with these small fish. Whatever be the explanation, there is no doubt of the fact that our university professors are more occupied in the effort to impart instruction and insure that the student derives some benefit from it than is the case in foreign universities. I have heard it said that whenever a group of European university men get together, they talk science, whereas we talk education. We are greatly concerned about the student, and largely about the poor student. This may be best in the circumstances, and I have no desire to attempt a rough and ready solution of so complicated a problem, but simply point out the undoubted fact that here is a factor in our comparative lack of scholarly production. With both the administrative and the educational interests so strong among us, we are prone to hover in the outskirts of scholarship, instead of plunging into the heart of it.

There is another aspect to the whole matter, for the universities are not the sole repositories and organizers of scholarship. Guilds of scholars have to be considered as a means of exciting to productivity. We have, indeed, few productive scholars outside of the universities, though this is at least partly due to the prestige which university professorships have among us, for it would be easy to name a score of scholars and scientific men who, though of independent means, have sought university connections, in order to have a definite standing in the scholarly world. College loyalty has been a strong force among us, and

the attachments of a professor have been mostly to his university rather than to the fellowship of his particular science Of recent years, with the organization of national scientific societies, some change has occurred in this respect It is to guilds of scholars, whether formally organized or not, that we must look for setting the standard of scholarly production The fellowship of scholars can only be a matter of gradual development, and their standards also must grow and can not be suddenly and artificially raised, but there is plenty of evidence that the standards of our scholarly guilds have been rapidly improving, and they will probably continue to improve Such guilds possess rewards and punishments of their own, for the standing of a man among his fellows is one of the strongest incentives to action The standards of the guilds must eventually be the standards of the universities, and thus we hold in our own hands, quite apart from the momentary attitude of university authorities, a force capable of raising the level of our own work and that of our successors

COLUMBIA UNIVERSITY

BIOLOGICAL TEACHING IN SECONDARY SCHOOLS

A MEETING of men interested in the advancement of biological teaching in secondary schools was held at the Harvard Union, Cambridge, on Saturday, February 4 Those present were Professor G H Parker, Harvard University; Principal Irving O Palmer, Newton Technical High School, Dr H R Linville, Jamaica (N. Y) High School, R H Howe, Jr, Middlesex School, Samuel F Tower, Boston English High School, S Warren Sturgis, Groton School, Head Master Frank E Lane and W L W Field, Milton Academy The relation of school biology to civics, the sequence of laboratory experiments, outdoor work with classes and college requirements were the topics informally discussed. The undersigned was authorized to communicate with other teachers with a view to establishing a series of conferences, perhaps to be held alternately in Boston and New York. Correspondence is accordingly invited from interested readers of this notice

SCIENTIFIC BOOKS

Questioned Documents A Study of Questioned Documents with an Outline of Methods by which the Facts may be Discovered and Shown By ALBERT S OSBORN With an Introduction by Professor JOHN H WIGMORE Two hundred illustrations Rochester, N. Y, The Lawyers' Cooperative Publishing Co 1910 Pp xxiv+501

"Questioned Documents" is an admirably clear presentation of the application by experts of modern scientific methods to the study of handwriting It gives a detailed exposition of the use in the identification of handwriting of enlarged photographs taken in various lights, of the document microscope and of the color microscope designed for recording the tints and shades of ink The instruments and appliances used in getting accurate measurements of such details of writing as the width of the line-stroke and the slant of various parts are also described Particularly interesting is the suggestion of the new application of stereoscopic photography in such a way as to determine in disputed handwriting the sequence of crossed lines, the time-relation of writing to folds in paper and the presence of erasures and changes in paper-fiber

The purpose of the book is practical—a very successful attempt to present the science of handwriting in relation to law, an attempt which constitutes a new and profitable departure in legal literature The author would arouse the interest of the trial lawyer in, and his intelligent comprehension of, the problems involved in questioned documents, so that he may be better qualified to deal with situations involving such matters. Those interested in the pure science of handwriting will, none the less, find much to learn from the author relative to its accurate measurement and analysis The reviewer is acquainted with no other

treatment of the subject from the practical standpoint as thoroughgoing and suggestive.

Since the psychology of individual variation in handwriting characteristics is still an unwritten chapter of the science, it is not surprising that the analysis of handwriting habits in the volume under consideration should be largely in terms of the writing system learned by the penman and of the writing instruments and material utilized by him. Such an analysis is accompanied by an historical account of the rise of various systems of handwriting and by a description of their characteristics. The dependence of many peculiarities of writing, such, for example, as shading, upon pen position, should be noted by the investigator of the subject. The author insists upon the use of a sufficient amount of proved handwriting as a standard for comparison in the case of a disputed document and records instances of normal variation in handwriting in such a way as to show forgery by a tracing-process in the case of unnatural uniformity. The interesting observation is made that individual writing habits are found to be revealed more clearly in minor details than in striking features, such as large capital forms. Possibly the author might, with profit, have treated at greater length variations in handwriting due to age, disease and emotional disturbance.

The author insists that the testimony of the handwriting expert should, if acceptable, be the expression not of an opinion founded upon more or less vague intuitions, but of a scientific conclusion from facts, a conclusion based upon reasons which are intelligible to the non-expert and presentable in court. The author is sceptical of testimony that concerns itself with the general appearance of handwriting rather than with accurate analysis and measurement. He is, naturally, amused by the pretensions of the graphologists who would read from handwriting the physical characteristics of the penman and catalogue therefrom his vices and virtues.

The application by the author of the methods used in identification of handwriting to the study of questioned typewriting shows a new field of inquiry, one that appears well worth working by the expert.

Tables for the Determination of Common Rocks. By Oliver Bowles, M.A., Instructor in Geology and Mineralogy, University of Minnesota. 16mo. Pp. vii + 64. New York, D. Van Nostrand & Co. 1910. $0.50.

This text is designed to meet the need of suitable tables for the determination of rocks and rock-forming minerals by microscopic methods and constitutes a convenient and useful pocket guide for field and laboratory purposes.

The usual classification of rocks is given but no attempt is made to group them in the tables accordingly. The grouping, based upon texture, is I., Glassy, II., Ashy or Cellular, III., Crystalline, even grained, IV., Porphyritic, V., Dense and Finegrained, VI., Banded, VII., Fragmental. The various types are arranged in the proper group and described briefly. In the case of crystalline rocks, mineral composition is made a basis for further subdivision and one chapter is given to tables for the determination of the more common rock-forming minerals, the classification being based upon color, hardness and cleavage.

The last chapter contains a short discussion of building stones. Terms used in the text are amply defined in a glossary at the end of the book.

SCIENTIFIC JOURNALS AND ARTICLES

The contents of the *American Journal of Science* for March are:

"Transmission of Light through Transparent Inactive Crystal Plates, with Special Reference to Observations in Convergent Polarized Light," F. E. Wright.

"Separation and Estimation of Barium Associated with Calcium and Magnesium, by the Action of Acetyl Chloride in Acetone upon the Mixed Chlorides," F. A. Gooch and C. N. Boynton.

"Feldspar Aggregate Occurring in Nelson County, Virginia," W M Thornton, Jr

"History of the Coconut Palm in America," O F Cook

"New Mink from the Shell Heaps of Maine," F B Loomis

THE first number of the new journal, *Phytopathology,* has just appeared This periodical is the official organ of the American Phytopathological Society It is to be published bimonthly and to be devoted to both the purely scientific and practical economic features of plant disease investigations The chief editors are Dr L R Jones, professor of plant pathology, University of Wisconsin, Dr C L Shear, plant pathologist, U S Department of Agriculture, and Professor H. H Whetzel, professor of plant pathology, Cornell University, who are assisted by twelve associate editors, representing different institutions and sections of the country The initial number contains 37 pages and 6 plates An excellent portrait of Anton de Bary, hitherto unpublished, appears in the frontispiece The following articles are included

"Anton de Bary" (with portrait), Erwin F Smith

"The Rusts of White and Red Clover," Frank D Kern

"Crown Gall of Plants," Erwin F Smith

"Fig Diseases," C. W Edgerton

"Floret Sterility of Wheats in the Southwest," Edw C Johnson

"Black leg or Phoma Wilt of Cabbage," Thos F Manns

"A New Fruit Spot of Apple," W M Scott

A KINETIC THEORY OF GRAVITATION[1]

EVER since Sir Isaac Newton enunciated the law of universal gravitation, more than two hundred years ago, philosophers have speculated on the nature of the mysterious agency which links every atom of matter in the universe with every other atom. Newton was unable to offer any adequate explanation.

Since Newton's time several theories of gravitation have been proposed, but all, of which I am aware, are open to strong objections and are not considered even promising by physicists

Study of the nature of gravitation is beset with unusual difficulties, because gravitation is ever with us and about us, it is the one universal phenomenon, and we can not escape from its influence—can not obtain any outside point of view

Gravitation is often described as a feeble force, and so it is, from one point of view It is difficult to measure, or even to detect, attraction between two small bodies But when the bodies are of planetary size the aggregate attraction of their molecules is enormous It is easy to calculate that the attraction between the earth and the moon, which is just sufficient to retain the latter in its orbit, would, if replaced by a steel cable, require that the cable be about five hundred miles in diameter in order to withstand the strain Between the earth and sun, the cable would have to be nearly as large in diameter as the earth, and attraction between the components of some double stars is millions of times greater than between the earth and sun (Lodge) So tremendous a phenomenon as gravitation, a phenomenon compared with which all others seem trivial, must have a mighty origin

That gravitation is a phenomenon of the all-pervading ether is beyond reasonable doubt This is so generally conceded that it need not be argued But how does the gravitative influence originate? how is it transmitted and maintained? what is the *mechanism* of gravitation? It is the purpose of this paper to attempt an answer to these questions

Let us consider what happens to a falling body We know that it gathers kinetic energy from some source, as evidenced by its acceleration; that this energy may do external work or develop heat, that the amount of energy gathered is measured directly by the distance fallen through (within the limits of uniform gravitation), irrespective of the time or rate of falling. When the distance fallen through is of inter-planetary magnitude, and the attracting body large, the gathered energy

[1] Read before the American Association for the Advancement of Science, December, 1910.

is enormous, sufficient, if converted into heat, to vaporize the most refractory falling body.

We are here confronted with the question, whence comes the energy acquired by a falling body? Certainly it was not inherent in the body before the fall, as evidenced by the fact that during unimpeded fall none of the physical or chemical attributes of the body, aside from the acquired motion, changes in the slightest degree.

We have been taught that before the fall the body was endowed with "potential energy of position," which is converted into kinetic energy during the fall. I think "energy of position" is an unfortunate term because it is so very inadequate. To me, it explains nothing. The case is not like that of a flexed spring, where there is internal molecular strain or displacement.

Let us imagine a pound-weight of iron, for instance, raised from the surface of the earth to a point near the moon, in a line joining the centers of the two bodies, the point so chosen that the opposing attraction of the earth and the moon shall exactly balance each other, leaving orbital motion out of consideration.

On the surface of the earth the pound-weight had some so-called "potential energy of position" because it was capable of falling into a pit, but in its new position near the moon, this potential energy not only has not been augmented, but has disappeared entirely, the pound-weight, left free to move, remains stationary. And yet we must have expended more than twenty million foot-pounds of energy in overcoming the attraction of the earth and lifting the weight to its new position. This amount of energy would be sufficient to impart to the weight a velocity more than ten times greater than that of the swiftest cannon ball, or, if converted into heat, would be many times more than sufficient to raise the iron weight to dazzling incandescence and then vaporize it. Now, in lifting the weight, this large amount of energy has disappeared utterly. We can not believe that the whole or any part of it has been annihilated; it must, in some form, be resident somewhere. I think no one will contend that this energy is resident, in any form, in the cold, motionless pound-weight. I believe it was absorbed by, and is now resident in, the ether through which the weight was raised. Conversely, if this be true, a falling body must acquire its energy from the ether through which it falls. This is a fundamental idea to which I invite attention. Faraday glimpsed it long ago, and others have appreciated it more clearly since his time. But, so far as I am aware, no one has realized its significance.

This view of gravitation implies that the ether is endowed with very great intrinsic energy in some form. Many scientists now hold that the ether is so endowed, and that the amount of this intrinsic energy is enormous. Sir Oliver Lodge[3] appears to regard this energy as potential in form, and estimates the intrinsic energy of a single cubic millimeter of the ether to be almost inconceivably vast. He says, "All potential energy exists in the ether." Sir J. J. Thomson says, "All kinetic energy is kinetic energy of the ether."

I conceive the ethereal energy involved in gravitation to be kinetic rather than potential, the latter involving strain or stress. Newton, and later Maxwell, assumed that bodies produce a stress in the ether about them, of such nature as to account for gravitation, but they were unable to imagine any physical cause for the stress.

All the past theories of gravitation of which I am aware, except the corpuscular theory of La Sage, appear to regard gravitating matter as the seat of the gravitative influence, the surrounding ether, by induced stress or otherwise, acting simply as the medium of transmission. I can not see that any of these theories accounts for the energy acquired by a falling body.

My own view of gravitation differs from these radically. I believe that kinetic energy of the ether is the fundamental cause of gravitation, and that a gravitating body plays a secondary rôle only, in disturbing the normally uniform distribution of the ether's energy, in a manner I shall endeavor to explain later.

[3] "The Ether of Space."

Let us assume, then, that the ether is endowed with very great kinetic energy normally uniform in distribution

Kinetic energy implies motion of something possessed of inertia Now, inertia is a fundamental attribute of the ether Sir J J Thomson holds that all inertia is inertia of the ether. The ether is highly elastic also, which, with its inertia, enables it to possess kinetic energy in wave form, as exemplified in radiation By the term wave, I mean progressive motion locally periodic, doubtless the ether as a whole is stationary Hence we may consider the kinetic energy of the ether as consisting in ether waves of some kind

These waves, vast in aggregate energy, eternal in persistence, without finite source or destination, are imagined as being propagated in straight lines in every conceivable direction This isotropic distribution of kinetic energy, essential to my theory of gravitation, was, for me, a difficult conception until I reflected that isotropic radiant energy is approximately realized in the interior of any furnace with uniformly heated walls

Any kind of waves capable of exerting motive action on the atoms or molecules of matter will fulfil the requirements, but I shall first consider the transverse, electromagnetic waves of radiation because these are the kind of ether waves we are familiar with

Of course intrinsic ether waves, if of the radiation kind, can not be of any frequency at present known to us as radiation, because then all bodies would become heated But we can easily imagine them of such extremely low frequency that the molecules or atoms of matter can not respond to them—can not vibrate in unison with them—molecular resonance can not be established, hence no conversion of the ether energy *directly* into heat in the ordinary way can take place

We are familiar with the dissipation or degeneration of the higher forms of energy into heat, and the continual degradation of heat to lower degree; that is to say, less violent molecular vibration and more general distribution As is well known, it is only through this degradation or running down of natural energy that we are enabled to utilize some of it Lord Kelvin called this function of energy "motivity" (we now call it entropy), and said the motivity of the universe tends to zero

We know that ordinary radiation waves in the ether persist indefinitely and without change of frequency or direction until they encounter matter, when they are absorbed and converted into heat, only to be radiated again, usually in longer waves, to some colder body This degradation of wave frequency continues until we can no longer follow it I beg to suggest that the ultimate destination of this wave energy is that vast reservoir of kinetic energy intrinsic to the ether We may liken the waves of radiant energy, which we apprehend as light and heat, to wind ripples on the surface of water, which continually degenerate in wave frequency until they are absorbed into and become a part of the mighty swell of the ocean.

Thus we may, perhaps, regard the ether's intrinsic energy as energy in its lowest form —Kelvin's zero of "motivity" But fortunately we may and do get some of this energy back in available form in several ways, as, for instance, when a falling body is arrested and develops heat, some of our wind ripples are then returned to us

When two gigantic astronomical bodies collide under the influence of gravitation, as sometimes happens, we witness in far distant space the birth of a nebula The inconceivably vast amount of heat developed by the collision converts both bodies into luminous vapor which expands with incredible rapidity into the nebulous cloud. This heat energy must in course of time degenerate back into the ether whence it came, though billions of years may be required, and during all this time the energy has "motivity" We may picture the stupendous result of the collision as only a local splash in the ether's mighty ocean of energy

Having postulated that the ether is endowed with very great intrinsic kinetic energy in wave form of some kind, that the waves are

propagated in straight lines in every conceivable direction, *i. e.*, the wave energy is isotropic, and that this energy is distributed uniformly throughout the universe except in so far as the distribution is disturbed by the presence of matter, I shall endeavor to explain my conception of the mechanism of gravitation.

For illustration in terms of the known, let us imagine a closed space having uniformly luminous walls of such character that every point on their surface radiates light in all internal directions. The enclosed space may be of any shape, but for the sake of simplicity let it be spherical or cubical, and large, say as large as a lecture room The space will be filled with isotropic radiant energy uniformly distributed—any cubic centimeter of space containing as much energy as any other

Next let us picture a small opaque body suspended anywhere in our luminous space The body may be of any shape we may imagine an atom or molecule to have, but, again for simplicity, let it be spherical—say a small grain of shot, and let it be located near the center of the space

The small body will absorb the light which falls upon it and will cast a spherical shadow, the depth or intensity of which will vary inversely with the square of the distance from the center of the body; and the shadow will extend to the confines of the enclosure, however large the latter may be. We can not perceive the shadow, but we know it is there. It is true that the body will soon acquire the temperature of its surroundings, and radiate as much energy as it receives, but for the purpose of this illustration let us consider only the high-frequency light energy.

As is well known, the ether waves of light will exert a slight pressure on the body. But in the case supposed, the pressure will be equal on all sides and no effort toward translation can result

Now let us introduce a second small body, similar to the first, and some distance from it. This, also, will cast a spherical shadow like the first. The two shadows will intersect, and each body will lie within the shadow of the other In other words, each body will be partially shielded by the other from the ether waves coming from that direction. Hence the light pressure will be less on that side of each body which faces toward the other than on the side which is turned away, and the bodies will be urged toward each other by the excess of light pressure on the sides turned away. This excess of pressure will vary with the inverse square of the distance between the centers of the bodies so long as the ratio of distance to diameters remains large

The ether waves concerned in gravitation can not, however, be like the light-waves I have just used for illustration, because light-waves heat bodies on which they fall, and their pressure is almost wholly superficial, it does not reach molecules much below the surface, and hence bears little relation to mass

But let us substitute for the short and feeble waves of light, powerful waves, still of the radiant kind, but of such great length and slow frequency that, as before explained, they do not excite the molecular vibrations which we appreciate as heat, and hence are not absorbed by matter, they pass freely through all bodies, bathing the interior molecules as effectually as those on the surface

Under these conditions each molecule or atom or unit of a gravitating body will have its own spherical shadow or field of influence, and the gravitative force acting on the body will vary directly with the sum of its units, *i. e.*, with its mass

The spherical shadow which I have pictured as the field of influence of each atom or material unit implies that the atom has caused, principally in its immediate neighborhood, a diminution of the ether's energy. Let us further imagine this subtracted energy resident in the atom as kinetic energy of translation in many paths, almost infinitesimally short and in every direction, but without collisions because neighboring atoms follow *very* nearly parallel paths We may then picture the collective atoms or molecules of matter buffeted about in every direction by the ether waves in which they are entangled, like a suspended precipitate in turbulent water.

Each atom or molecule may be regarded as a center of activity due to its kinetic energy of translation, with continual absorption and restitution of the ether's energy, normally equal in amount The manner in which this molecular activity maintains, in effect, the supposed spherical shadow requires explanation which I shall attempt in a future paper

Of the several components into which the composite motion of each atom can be resolved, that one lying in the direction of an attracting body will be the greatest, because the waves from that direction, being partially intercepted by the attracting body, are weakest; and the atom will be *pushed* in that direction by the superior waves behind it If free to fall, the atom will continually absorb more energy from the stronger waves behind it than it restores to the weaker waves in front, and will thus acquire additional kinetic energy of translation in the line of fall, measured directly by the number of waves involved, *i e*, by the distance moved Conversely, if the atom be forced away from the attracting body, restitution of energy will exceed absorption, and the energy expended in moving the atom against attraction will be transferred to the ether

It will be seen that gravitation is a *push* toward the attracting body, and not a pull It is clear, also, that the velocity which a falling body can acquire tends asymptotically to a limit, which is the velocity of the ether waves which push it—the velocity of light, if transverse waves are involved.

I have already intimated that any kind of ether waves capable of imparting motion (not internal vibration) to the atoms of matter will fulfil the requirements of my theory, but have thus far discussed only transverse waves.

Let us now consider longitudinal waves—waves of compression and rarefaction, like sound waves in air and in elastic liquids and solids The "spherical shadow" conception which I have employed in connection with transverse waves applies equally well here

So far as I am aware, longitudinal waves in the ether are unknown, but that such waves have not been observed is not convincing argument that they do not exist

Assuming then that some, or perhaps much, of the intrinsic energy of the ether is embodied in longitudinal waves, we have only to find some motive action of such waves on atoms of matter to account for gravitation Adequate motive connection may perhaps be effected by the locally alternating flow and ebb—acceleration and retardation of the ether in which the atoms are enmeshed, incident to its wave motion We have ample reason for believing that the ether does obtain a grip of some sort on the atoms of an accelerating (falling) body, and a retarding (rising) body, from which it follows that accelerating and retarding ether, as in a wave of compression, must grip a comparatively stationary atom

Certain facts of astronomy apparently require that gravitational attraction between bodies, however distant from each other, must, in effect, be instantaneous, that is to say, the line of apparent attraction between them is a straight line joining their centers I believe my theory meets this condition, but I shall reserve discussion of the point for a future paper

I feel much diffidence in presenting the foregoing rough draft of a theory of gravitation, but I can not avoid the belief that it contains some germs of truth, perhaps the real key to the great mystery, though, if this be true, I have, no doubt, used the key clumsily and imperfectly

If the ether-wave theory of gravitation is, in the main, the true one, it offers some hope of experimental verification. Provided the waves are of one principal frequency, or even of several, we may find something, doubtless of molecular magnitude only, which will oscillate in unison with them so that resonance can occasionally be established and a cumulative effect obtained sufficient to manifest itself as heat

In searching for some natural phenomenon of this nature, I thought of the thermal condition of the upper atmosphere as a possible case. The mean molecular velocity of a gas at some temperature, in connection with the

mean free path of its molecules at some particular pressure or pressures, may possibly afford the necessary conditions for fortuitous resonance, with development of some slight amount of heat by the increased violence of inter-molecular collisions I have done much experimental work on these lines during the past year, but, notwithstanding refinement of method and manipulation, the results have thus far been unsatisfactory The work is still in progress, however, and investigation of other phenomena is contemplated

CHARLES F BRUSH

CLEVELAND, OHIO

AMERICAN SOCIETY OF ZOOLOGISTS EASTERN BRANCH

THE Eastern Branch of the American Society of Zoologists held its annual meeting on December 27-30, 1910, inclusive, at Cornell University, Ithaca, N Y, in conjunction with the American Society of Naturalists, the American Association of Anatomists and the Society of American Bacteriologists

The following officers were elected

President—H V Wilson, University of North Carolina.

Vice president—H E Crampton, Columbia University

Secretary treasurer—Raymond Pearl, Maine Agricultural Experiment Station

Additional Member of Executive Committee—R G Harrison, Yale University

The following persons were elected members of the American Society of Zoologists at this meeting Dr Alice M Boring, University of Maine, Dr O A Johannsen, Maine Agricultural Experiment Station, Professor R E Sheldon, University of Pittsburgh, Professor A E Lambert, State Normal School, Framingham, Mass, Dr R C Schiedt, Franklin and Marshall College, Dr Sergius Morgulis, Harvard University, Professor E W Gudger, State Normal College, Greensboro, N C, Dr A M Banta, Carnegie Institution, Station for Experimental Evolution, Professor G G Scott, College of the City of New York

A committee was appointed to prepare a resolution on the death of Professor C O Whitman This resolution will be published in a later number of SCIENCE

The following papers were presented at the meeting, either in full, or by title

The Spermatogenesis of the Opossum· H E JORDAN, University of Virginia.

An accessory chromosome and chondriosomes are the structures of special interest Metaphase plates of dividing spermatogonia contain 17 rod-shaped chromosomes (diploid group, 16 autosomes, 1 monosome) A chromatin- (chromosome) nucleolus is present during the growth period (including synizesis and synapsis) invariably at that point near the nuclear membrane next the centrosphere The first numerical reduction results from a pairing end to end (telosynapsis) of the 16 autosomes The haploid chromosome group thus contains 9, the accessory recognizable by its larger size and bipartite form During metakinesis (reduction division) the accessory chromosome passes undivided, and in advance of the ordinary chromosomes, to one pole Two types of secondary spermatocytes result one with 9, the other with 8 chromosomes During the brief resting phase one type has a chromatin nucleolus, the other lacks this structure A second numerical reduction has occurred—a phenomenon, previously described by Bardeleben (1898) for man, and quite recently by Guyer for certain birds—giving rise to hemioid groups containing 5 and 4 chromosomes, respectively The ensuing division is equational In the early spermatid-phase a resolution takes place giving 9 and 8 chromosomes, respectively A dimorphism of spermatozoa thus results Chondriosomes (mitochondria) appear in early postsynaptic stages (probably as chromidia passed out of the nucleus) A direct continuity is demonstrable between the chondriosomes and the spiral filament of the middle piece of the spermatozoon No twin spermatozoa, such as Selenka described in the vas deferens of the opossum, appear in the testis studied

The complete paper will appear in the *Archiv für Zellforschung*

The Germ Cell Determinants of Beetles' Eggs ROBERT W HEGNER, University of Michigan

This report is based on the results of experiments in killing parts of the eggs of some chrysomelid beetles The posterior ends of freshly-laid eggs contain a disc shaped mass of granules that stain like chromatin. These granules are taken up by the cleavage products that encounter them, these cleavage products later become germ cells For this reason the granules have been called germ cell determinants When the posterior ends of freshly-laid eggs are killed with a hot needle, thus preventing the granules from taking part in

development, the resulting embryos do not develop germ cells. This evidence strengthens the hypothesis that these granules are really germ cell determinants.

The complete paper will be published in the *Biological Bulletin*.

Heterochromosomes in Mosquitoes: N. M. STEVENS, Bryn Mawr College.

An unequal pair of heterochromosomes is found in the male germ cells of *Anopheles punctipennis*, and the heterochromosome differentiation can be seen in the resting spermatogonia and in the spermatids as well as in the spermatocytes. In *Culex pipiens*, *Culex tarsalis* and *Theobaldia incidens* no such differentiation of heterochromosomes is present. As the sex determining mechanism is without doubt the same in the several species of mosquitoes, it is evident that heterochromosome differentiation is not a necessary factor in the determination of sex. In *Culex* and *Theobaldia* we certainly can not say two X chromosomes give a female and one X chromosome or an X and a Y chromosome give a male, for there are no X or Y chromosomes. However, it is evident that, although the heterochromosome differentiation may have nothing to do with sex-determination, the sex determining factors must be closely correlated with it, and may in some cases be located in the heterochromosomes. The importance of a study of the origin and history of the heterochromosomes apart from the idea of sex determination is urged. The complete paper will be published in the *Biological Bulletin*.

Origin and Significance of Mitochondria: T. H. MONTGOMERY, JR., University of Pennsylvania.

(An excerpt from a paper to be published in the *Journal of Morphology* on the spermatogenesis of *Euschistus*.)

The mitochondria undergo their chief growth and multiplication in the growth period of the germ cells, and are few or absent in the spermatogonia. Their mode of division in the reduction mitoses is irregular, and they become divided by the cell constriction. They do not arise as eliminated chromatin nor from the allosomes, but apparently as a chemical interaction of nucleus and idiosome. They represent part of the epigenetic history of the germ cells, and the chromosomes the preformistic.

The Method of Cell Division in Moniezia: A. RICHARDS, Princeton University. (Introduced by Ulric Dahlgren.)

A reinvestigation of the development of the female sex products of *Moniezia* has not substantiated the claim of Child that amitosis has a regular place in this development. Amitotic divisions were found at no stage in the growth of these products. On the other hand, mitoses occur at all stages in the development, although more rarely in the early oogenesis than might have been expected. Probably also periodicity of mitotic divisions is one reason for the relative scarcity of spindles at this stage. Cleavage divisions are positively mitotic for the spindle in each cell generation may be found. The complete paper will appear in the *Biological Bulletin*.

The Relation between the Formation of the Fertilization Membrane and the Initiation of the Development of the Echinoderm Egg: J. F. MCCLENDON, Cornell University Medical College.

Loeb observed that the sea urchin's egg may develop without the formation of a fertilization membrane, and I have confirmed this observation, and shown that Harvey is very probably wrong in his supposition that this is a case of failure in "pushing out" of the membrane. Therefore I concluded that "membrane formation" is not essential for the segmentation of the egg, although by furnishing protection it may insure the development of the embryo.

Loeb postulated that an osmotically active colloid exists in the unfertilized egg, but is so covered with lipoids that it does not absorb water until it is squeezed out or otherwise exposed at the surface of the egg, at the beginning of development (when it fills the so called "perivitelline space"). I have shown[1] that this substance bears a positive charge (is basic) since it migrates toward the kathode when an electric current is passed through sea water containing the fertilized egg.

The unfertilized egg is imbedded in a mass of jelly which is probably mucin. This jelly bears a negative charge (is acid) since it combines with color bases.

When the positively charged colloid is exposed at the surface and comes in contact with the negatively charged jelly, the two mutually precipitate at their surface of contact, thus forming the fertilization membrane. But if all of the jelly is washed off of the egg before the latter is caused to develop, no fertilization membrane is formed (as I have observed) because no two oppo-

[1] *Am. Jour. Physiol.*, 1910, XXVII., 240.

sitely charged colloids are brought in contact, but the basic colloid may with difficulty be seen as a refractive layer, which has been mistaken for a poorly developed "fertilization membrane."

The increased permeability of the egg surface, which releases the basic colloid, is one of the prerequisites to the increased oxidation of the developing egg, and in this way membrane formation and development are induced by the same change.

Evidence for the Transmission of the "Wound Stimulus" to Underlying Tissues and its Relation to Regeneration: J. F. McClendon, Cornell University Medical College.

The "current of injury" produced by the negative electric potential of a wounded surface is common to animal and plant tissues. The wounded cell acts as an electric generator and a current flows through neighboring cells. If a current is passed through living tissue, which is subsequently fixed and stained, basophile substances will be found displaced toward the anode. In sections of tissue adjacent to a wound the extent of the current is indicated by the displacement of basophile granules. The current affects first the cells in contact with the wounded cells, then extends in some directions more than others. Electric currents (currents of growth) continue for many days after the wound has healed. Since electric currents cause sea urchin eggs and tissue cells to divide and proliferate, probably these bioelectric currents constitute the so-called "formative stimulus" of regeneration.

Maturing Reagents and those Inducing Segmentation in Artificial Parthenogenesis: Max Withrow Morse, Trinity College.

An extended series of experiments, continued throughout the summer at the Harpswell Laboratory upon the eggs of *Cerebratulus*, demonstrated that those reagents which induced maturation of this egg, would not cause development to proceed farther through the segmentation stages and indeed evidence for an inhibiting action to segmentation on the part of the solutions used in causing the egg to throw off the polar bodies, was obtained. The glucoside saponin, dibasic acids such as oxalic, hydrochloric and tartaric acid were used successfully to mature the egg, but no subsequent application of these reagents caused segmentation to proceed. It was found, however, that if every trace of these solutions was removed by careful washing and the eggs placed in a CO_2 sea water solution, with a concentration of approximately 0.19 g. to the 100 g. sea water, segmentation proceeded. However, no method was found whereby the eggs could be carried beyond the later segmentation stages. Loeb and others have observed this antagonistic action of maturing and segmentation-producing reagents in other forms, and in such cases, as in the present one, the reactions are not reversible, CO_2 will not cause maturation. The experiments were checked against temperature, salinity, alkalinity and such external factors as might modify results.

Newly Found Odonate Larvæ of Special Interest from Costa Rica: P. P. Calvert, University of Pennsylvania.

The larva of *Cora* possesses two-branched mandibles, and paired ventral tracheal gills (= modified legs?) on abdominal segments 2–7, in addition to three thick caudal tracheal gills. A detailed account has appeared in *Entomological News* for February, 1911.

The larva of *Mecistogaster modestus* lives in the rain water between the leaf bases of arboricolous bromeliads. The remarkable increase in length at transformation, from the larva measuring 24 mm. long to the adult 82 mm. long, occupying about one and a half hours, was illustrated by a series of lantern slides from life. The full description will probably be published in the journal quoted above.

The Chondrocranium of Eumeces (preliminary report): Edward L. Rice, Ohio Wesleyan University.

Preliminary comparison with chondrocranium of *Lacerta* as described by Gaupp. For most part these skulls are very similar, but with some striking differences. Particularly striking is enormous size in *Eumeces* of pars cochlearis of otic capsule. This extends far down into region of basal plate, displacing facialis foramen relatively upward between the two parts of otic capsule.

In no single stage is lateral wall of temporal region so complete as in *Lacerta*, although all the same elements may be recognized in a comparison of various stages, some parts being in regression while others are progressively developing. In earliest stages tænia parietalis media extends upward and backward to unite with tænia marginalis, thus dividing fenestra prootica into upper and lower portions, latter furnishing exit for trigeminal nerve.

Cartilage of interorbital septum continuous in younger specimens; progressively fenestrated in later stages.

Nasal capsule in general less complete than in

Lacerta, but large fenestra lateralis nasi, emphasized by Gaupp, wanting in all stages

Considerable individual variation in arrangement of nerve foramina Without reference to age, hypoglossus foramina may be either three or two on each side, or three on one side and two on other Also irregularities in course of abducens

Discussion of columella auris deferred

The Taxonomic Value of the Brain B G WILDER, Cornell University

That the brain presents distinctive characters in certain teleostean families was claimed by L Agassiz in 1844[1] The taxonomic value of encephalic characters has been maintained at different times by Owen, Gill and the writer Nevertheless, recent revisions of various groups do not even mention the brain, and four years ago a review[2] by a former secretary and vice-president of the zoologic section of the American Association for the Advancement of Science declares that the study of the nervous system has no value from any other point of view than that of function The present paper mentioned instances of generally accepted groupings that might have been based upon the brain alone, recalled malassignments (*e g*, of the Sirenia with the Cetacea, of ganoids and selachians as *Palæichthyes*) that might have been averted by due consideration of the brain; and held that such consideration forbade the association of ganoids and dipnoans as a "ganoid dipnoan phylum," warranted the separation of lampreys and hags as coordinate groups of class grade, and showed that *Pristiophorus* is a primitive type not nearly related to *Pristis* Standard treatises evince indifference toward the brain or ignorance of it, and are open to criticisms comparable with those in the *American Journal of Science*, Vol 20, July, 1880, p 76, likewise the commingling of constant and peculiar characters with others not really distinctive, as deprecated in 1885[4] and in 1894[5]

The Histology of the Oviduct of the Domestic Fowl FRANK M SURFACE, Kentucky Agricultural Experiment Station

The Lampreys of the Cayuga Lake Basin Fate of Lampreys after Spawning, Non-parasitism of the Brook Lamprey SIMON H GAGE, Cornell University

After spawning, lake lampreys were put into wire cages with live cat fish The cages were kept in the running water of the stream where they spawned, and in the lake water at the Limnological Station The spent lampreys never fed upon the cat fish, and soon died Dead bodies of lampreys were found in great abundance along the stream The discovery was made that the notochord is very persistent, enduring in full perfection after all the rest of the animal had decayed There seems great probability that under favorable conditions the notochords might become fossilized, if so they would puzzle the paleontologist.

The non parasitism of the brook lamprey was first reported by me in 1898 The demonstration has been repeated during the years 1907, 1908 and 1909, by keeping the transforming animals over winter in an aquarium They live under the sand like the ammocœte, and only emerge in the spring when their sexual products are ripe Lake lampreys when they transform attack fish with great ferocity, and suck their blood, but the brook lamprey never attacks fish under the most favorable conditions When they emerge from the sand they lay their eggs and die From their structural adaptation to parasitism it is believed that they were once parasitic, but have lost that habit

Protective Coloration in Poultry RAYMOND PEARL, Maine Agricultural Experiment Station

This paper has appeared in the *American Naturalist* for February, 1911, under the title "Data on the Relative Conspicuousness of Barred and Self colored Fowls"

Adaptive Color Changes in Flounders. F B SUMNER, U S Bureau of Fisheries.

The author described the results of some inquiries, conducted at Naples and Woods Hole, into the relation between the visible background and the color shade and pigment-pattern assumed by the fish

Sense of Smell in Selachians. R. E. SHELDON, University of Pittsburgh (Introduced by S H. Gage.)

1 A current of water, caused by the respiratory movements, and augmented by the forward motion of the fish in swimming, courses through the nasal capsules of the dogfish

2. By this means substances in solution in the water come in contact with the olfactory mucous membrane.

3. Dogfish recognize and determine the location of food substances through a chemical sense.

4. This power is lost when the olfactory capsules are filled with loose cotton. It is regained when the cotton is removed.

5. The plugging of one nostril only does not seriously affect this power.

6. The dogfish obtains its food almost, if not entirely, through the use of the sense of smell.

7. The selachians possess a true sense of smell, comparable to that of the terrestrial vertebrates.

The complete paper will appear in the *Journal of Experimental Zoology*.

Habits and Reactions of the Ciliate, Lacrymaria: S. O. Mast, Goucher College.

Lacrymaria is usually found with the body well concealed in débris while the head stretches out in all directions and moves rapidly about forward and backward and from side to side apparently exploring every nook and crevice within its reach which often extends to a distance equal to eight times the length of the body. In this way the creature captures other organisms on which it feeds. It never swallows dead particles, showing that it exercises the power of selection in the process of feeding.

It is usually assumed that the movements are regulated by the contraction of tissue in the neck and body, but this is not true. The head is not thrust out, it is pulled out. Nearly all of its actions are due to the activity of a band of powerful cilia which extends around the mouth. Thus *Lacrymaria* is much like an organism composed of two independent parts united by means of an extremely elastic substance far more elastic than any known lifeless material. When the neck is fully extended it is frequently fifty times as long as when contracted.

There is no indication of orientation in *Lacrymaria* under any condition. It does not respond to light. None of its reactions fulfil the demands of any of Loeb's definitions of tropisms. The movement of the entire organism is almost entirely regulated by the reactions of the head, and the direction of movement of the head is regulated almost entirely by internal factors, it is practically independent of the location of the stimulus. We assume that all of the reactions in this animal are definitely determined by physico-chemical processes, but whether they are or not has by no means been demonstrated.

The complete paper will probably be published in the *Journal of Animal Behavior*.

The Reaction System of the Flagellate, Peranema: S. O. Mast, Goucher College.

Under natural conditions *Peranema* rarely swims. It ordinarily moves in contact with the substratum without rotating. Only the tip of the flagellum is active. This is bent at right angles to the rest and strikes strongly backward. When the organism is stimulated no matter by what means or at what point it responds by turning the anterior end with the flagellum sharply, always toward the same side. Then it straightens out and proceeds on a new course usually at an angle of about 90° with the old. If the stimulus does not cease the same reaction is repeated until it does. This is the only method which *Peranema* has for changing its course in its usual method of locomotion. The action of the flagellum is not functional in this. If strongly and repeatedly stimulated a larger portion of the flagellum may be brought into action and there may be peristaltic contractions in the body. Both of these processes affect the rate of motion but not the direction. The direction of turning is entirely dependent upon internal factors, it is independent of the location of the stimulus on the body. The direction of movement is not definitely determined by external factors. It is dependent upon "trial" positions which are assumed by turning the anterior end in response to a stimulus, only such as do away with the action of the stimulus are followed up.

The complete paper will probably be published in the *Journal of Animal Behavior*.

The Behavior of Certain Arthropods in Relation to Color Environment: A. S. Pearse, University of Michigan.

As a result of experiments with crayfishes, caddis-fly larvæ, spider crabs and spiders the conclusion is drawn that protectively colored arthropods do not select an environment similar to their own, at least they do not make such selection on account of color.

The complete paper will be published in the *Journal of Animal Behavior*, Vol. I., pp. 79–110.

On the Regenerative Power of the Dissociated Cells in Hydroids: H. V. Wilson, University of North Carolina.

It had been shown that when certain sponges are broken up into their constituent cells, the cells will reunite and form masses capable of differentiation into functional sponges. Two hydroids, *Pennaria* and *Eudendrium*, were found to possess the same power. The dissociated cells

and small cell aggregates fuse and give rise to lumps, which become smooth and secrete a perisarc. Their size and shape are within control. Such bodies are solid masses in which cell limits exist, although the structure may be in part syncytial. They show at first but little change and are subject to great mortality. After two or three days many throw out one or more cylindrical outgrowths in which ectoderm and entoderm are differentiated. In the case of some of these, growth and differentiation continue until the end of the outgrowth is transformed into a perfect hydranth.

Masses resembling those just described were obtained in a similar way from an alcyonarian, *Leptogorgia*, and when the immature gonad of *Asterias* was broken up, the cells quickly fused, forming lumps and plates. Probably the power to fuse resident in the cells and cell aggregates into which a body (in the case of lower metazoan) or tissue (in case of higher form) may be broken up is wide spread. What degrees of regenerative power may be resident in such masses is a matter for investigation. (Paper to appear in the *Journal of Experimental Zoology*.)

The Problem of Form in Hydra: HERBERT W. RAND, Harvard University.

In the problem of form as presented in ontogenesis we have progressed so far as to be able to state confidently that the essential form determining factors are within the organism itself. We must now discover to what extent and where in the organism these formative agencies are localized. The line of attack upon this problem lies in experiments involving various derangements of the normal form of relatively simple organisms. The available morphogenetic data upon *Hydra* probably exceed in quantity and diversity those upon any other equally simple organism.

An examination of the total evidence afforded by *Hydra* leads to the conclusion that in the normal adult the peristome is the seat of some peculiarity by virtue of which that region exercises formative control over column substance, whether it be substance of the column to which the peristome originally belonged, or of any other column with which the peristome material comes into relation by transplantation. When a piece of column regenerates a head, this form controlling condition is established in the prospective peristome material in advance of the visible formation of oral organs and as a prerequisite of it (Browne, 1909). *This localizing of the formative agencies is a function of the whole of the regenerating piece.* In the normal hydra, therefore, heads are not, in any direct sense, preformed at various levels of the column.

In graft compounds having two or more heads, the regulatory changes may, without exception, be interpreted as dependent upon competition of the several peristomes for control of the column substance.

The phenomena of regeneration and regulation fairly compel the assumption of the existence of a specific formative force system for which those particular chemical complexes which constitute hydra substance serve as the vehicle, and, together with the phenomena of polarity, they afford ground for some conception of the distribution and mode of operation of such a force system. (A full treatment of the subject is being prepared for publication.)

The Proportion of Male-producers in Hydatina senta as Affected by External and Internal Factors: A. FRANKLIN SHULL, Columbia University.

The proportion of male producers in the rotifer *Hydatina senta* can be reduced by rearing the animals in weak solutions of urea, several ammonium compounds, beef extract or creatin. Since some of these substances exist in the food cultures used in the experiments, starvation may appear to increase the proportion of male producers because smaller quantities of these substances are administered with the food.

Different pure lines of rotifers obtained from widely separated localities yielded different proportions of male producers when reared under the same conditions; this indicates the existence of an internal factor that plays a rôle in determining the proportion of male producers. When individuals belonging to distinct pure lines were crossed, the offspring gave rise to pure lines (F_1) yielding more male-producers than either parent line. When a member of one of these F_1 lines was crossed with an individual from one of the parent lines, the zygote gave rise to a line (F_2) producing a proportion of male producers intermediate between those of its two parent lines. The explanation of these results is not yet clear. (To be published in the *Journal of Experimental Zoology*.)

Evolution of Hectocotylism among Cephalopods: G. A. DREW, University of Maine.

The paper read will be included in a paper bearing the following title: "Sexual Activities of the Squid, *Loligo pealii* (Les.)—1. Copulation, Egg laying and Fertilization." It is to be pub-

lished in the *Journal of Morphology* during the year of 1911

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

SECTION D—MINNEAPOLIS MEETING

The section held its meetings on Thursday and Friday of convocation week The Thursday morning session was devoted to the routine business connected with election of officers and fellows and to a program of papers, ten in number, of which eight were devoted to road and highway problems These papers were interesting and valuable contributions and should have been heard by a much larger audience than were in attendance

Thursday afternoon the section met in joint session with Section B and listened to the address of retiring Vice president Hayford of Section D on the subject "The Relation of Isostasy to Geodesy, Geology and Geophysics" and to that of Vice president L. A. Bauer, entitled, "The Broader Aspects of Research in Terrestrial Magnetism" Both addresses have been published in full in Science and are well worth reading by those who heard them at the meeting as well as by others interested in the subjects These sections have ever been fortunate in their vice presidential addresses

Thursday evening was given over to a dinner and smoker for the members of Sections A, B and D and the Chicago Section of the American Mathematical Society The dinner was served by the Commercial Club of Minneapolis The post-prandial remarks were enjoyed and enjoyable

Friday morning Section D held a session devoted to Aeronautics at which nine papers were read by or for the authors Quite appropriately the program opened with an appreciation of Dr Octave Chanute written by James Means, of Boston, and presented by Professor A. Lawrence Rotch, vice-president of the section This contribution will be printed in full in Science On Friday afternoon, Sections A, D and the Chicago Section of the American Mathematical Society met in joint session for a symposium on engineering mathematics, the same being a discussion of a preliminary report on the subject prepared by a committee appointed at the time of the Chicago meeting of the American Association for the Advancement of Science Printed copies of the report had been prepared by the chairman of the committee, Professor E. V. Huntington, of Howard University, who opened the discussion, which was continued with spirit during the entire session with profit to all present.

Professor A. Lawrence Rotch, vice-president of

the association and chairman of Section D, presided at all meetings of the section and at the joint session of Sections B and D

The officers for the Washington meeting of the section are as follows

Vice president—C S Howe, Case School of Applied Science

Retiring Vice president—A Lawrence Rotch, Blue Hill Observatory

Secretary—G W Bissell, Michigan Agricultural College

Member of the Council—A F Zahm, Washington, D C

Member of General Committee—O F Marvin, University of Kansas

Sectional Committee—T E Boyd, Ohio State University, A H Blanchard, Brown University, C M Woodward, Washington University, W J Humphreys, Mount Weather Observatory, G O Squier, U S A

Herewith are titles and abstracts of the papers presented

The Amount of Stream flow in the Northern Prairies E F CHANDLER, University of North Dakota.

In the prairie regions of the northern United States, there have been until lately no stream-flow records available Within the past decade, the U S Geological Survey and other agencies have maintained fairly extensive records here It is now known that in this region the stream-flow or "run off" is far less than formerly supposed In North Dakota, as a particular example, it is seen that some former estimates were as much as 500 per cent in error, for the average annual run off is less than one inch and the total of a single year is frequently less than one half inch

The run off from any drainage area depends upon its topography, geological structure, etc, and upon its total rain fall and the seasonal distribution and intensity of the rains But where the run off is as small as here considered, it is very improper and misleading to follow the frequent custom of speaking of the run off as a *percentage* of the rainfall

The only basis upon which any reasonable estimates can be made is a comprehensive set of rainfall and stream flow records extending through a long period of years Rain fall records alone are not sufficient, this statement applies especially to regions where the stream flow is only a small percentage of the rainfall

Consequence of Solution of Air in the Hydraulic Air Compressor F W MCNAIR and GEO A KOENIG, Houghton, Mich

Brief description of the Taylor compressor at the Victoria Mine, difficulty with lights in the mine, plan of the mine, conditions due to "compressor air" as affecting lights and men, comment on efficiency of compressor, desirability of further investigation, being a brief résumé of the results of an investigation made in the spring of 1907 by the authors

A Comparison of English and American Traffic Regulations A H BLANCHARD, Brown University, and H B DROWNE, Providence, R I

From the standpoint of the highway engineer the following regulations should be made a part of the laws relative to the use of highways by various kinds of traffic The proposed regulations are based on conclusions arrived at after a careful consideration of the effect of various classes of traffic on road surfaces as exemplified by American and European practice

1 All horse drawn vehicles shall be equipped with a light or lights

2 All vehicles, either horse drawn or motor driven, having iron tires and using the improved state roads shall be provided with tires of widths such that for a 2 foot wheel 500 pounds shall be the maximum pressure per linear inch of width per wheel, but an additional pressure of 30 pounds per inch shall be allowed for each additional 3 inches in diameter The maximum width of tires for horse drawn vehicles shall be 6 inches All iron tires must be smooth The width out to out of all classes of vehicles, including the superimposed load, shall not exceed 8 feet

3 The maximum speed of motor cars on all highways shall not be greater than is reasonable and proper, having regard to all classes of traffic and local environment

4 Vehicles shall be so constructed that the driver or operator shall sit on the left rather than on the right

5 Motor cars (including traction engines) hauling trailers shall keep to the right side of the center of the road No more than three trailers shall be allowed in any train Pneumatic tires or tires made of soft or elastic material shall not be equipped with chains, metal studs or some other non skidding device of this character except in the case of passenger vehicles carrying not more than seven persons

6 The intensity of powerful acetylene lights on motor vehicles, including those running on rails, shall be diminished on the approach of other vehicles

7 Sign posts shall be erected by the state highway departments to give notice of points of danger and to give information as to the route of the road

Relation between Modern Traffic and the Alignment and Profile in Highway Design H B DROWNE, Providence, R I

Preliminary to designing a road, a careful study should be made of the existing traffic conditions and those to be expected, since there are several features in the design that depend upon whether a road is to serve only a horse drawn vehicle traffic, a combination horse-drawn vehicle and motor car traffic or a motor car traffic alone Wider roads are required where there is much motor car traffic and on important roads a minimum width of twenty feet is advocated Also the transverse slope or crown of the road should be made from one fourth inch to one half inch per foot Sharp curves are not detrimental to a road that takes mostly a horse drawn vehicle traffic, but if a heavy motor car traffic is expected all bad curves should be eliminated or reduced as much as possible, since they are not only expensive to maintain but are also extremely dangerous Moreover, the curves should have a one way slope up from the inside edge, as this will distribute the wear more evenly over the entire width of the road There is no need of reducing the maximum grades now in common use on the improved roads

The Present Status of the Use of Bituminous Materials in the Construction and Maintenance of Roads in the United States A H BLANCHARD, Brown University

As an indication of the development of the use of bituminous materials in road construction and maintenance, statistics are submitted based on the work accomplished by the state highway departments of Maine, Maryland, Massachusetts, New Hampshire, New Jersey, New York and Rhode Island The total amounts of bituminous work in the various years are as follows 1908, 350,000 sq yds; 1909, 7,750,000 sq yds; 1910, 18,000,000 sq yds.

The most notable developments have been (1) In the increased use of liquid asphalt and heavy asphaltic oils for surface treatment as is shown by the following figures, 1908, 208,000 sq yds, 1910, 2,434,000 sq yds (2) In the increased use of light oil as a dust layer, as is indicated by its non employment in 1908, while 9,825,000 sq yds were treated in 1910 (3) The extensive use of asphalts, solid at ordinary temperatures, or combinations of asphalt and tar in connection with the penetration method of constructing bituminous pavements, the total square yards built in 1910 being 4,400,000 sq yds, while no work of this character was done in 1908 (4) The increase in the use of liquid asphalts and heavy asphaltic oils in the construction of bituminous pavements by the mixing method, as is shown by the following figures, 1908, 3,000 sq yds, 1909, 151,000 sq yds, and in 1910, 335,000 sq yds

Also attention is called to the more general use of refined tar in place of crude tar, the increased use of mechanical distributors both in the surface treatment of old roads and the construction of bituminous pavements by the penetration method and the introduction of mixing machines in connection with the construction of bituminous pavements by the mixing method on state highway work

Certain Considerations affecting the Selection of Bituminous and Mineral Matter for Road Construction and Surface Treatment J O TRAVILLA, St Louis, Mo

Highway engineers are giving much attention to the investigation of bitumens and to the development of specifications for bituminous materials, but in the opinion of the writer insufficient attention is paid to the study of the mineral aggregate The life of an asphalt or bitulithic pavement has been shown to depend upon the character of the aggregate to a great extent, and in the case of bituminous concrete or a bituminous wearing surface the same is true

In general mineral dust is as objectionable as moisture in the construction of bituminous roads

The wearing qualities of the mineral matter employed affect the life of a road and also the form of construction In the case of a very soft stone better results ensue when the larger stone is placed on top.

The writer's experience proves to him that resiliency in the surface is of importance in lengthening the life of a road or pavement Bitumens should, therefore, not be brittle at low temperatures nor should they be too soft at high temperatures St Louis has specifications governing the special adaptability and the methods of application for surface treatment of four grades of oil

Care should be taken to keep oiled streets clean The oiling of all road intersections is important in this connection.

Need of and the Opportunity for Technically-trained Men in Highway Work A N JOHNSON, Springfield, Ill.

This paper reviews briefly the history of road

building in the United States, noting that from the time of the advent of railroad construction, little or no attention was given by engineers to road work until about 1890, when some of the eastern states took up the question of road improvement from state-wide view points, since which time large sums of money have been appropriated by different states for the systematic study and construction of roads, that this work is now demanding the service of trained men and the people generally are realizing the necessity of such service

In presenting the paper, the writer illustrated with lantern slides some of the conditions found in highway work in Illinois and the methods of the road and bridge construction undertaken by the Illinois Highway Commission which would be representative of the conditions and methods applicable to a wide area of the Mississippi Valley region

Methods of Taking Traffic Census on Highways A H BLANCHARD and I W PATTERSON, Providence, R I

The value of statistics relative to traffic on highways, taken previous to their construction, is generally admitted, but the methods to be employed in the securing of such statistics have not been discussed in the technical press except relative to the classification of traffic

In view of the fact of their close relation to the wear of a road surface, the following elements of classification should be noted differentiation between horse drawn and motor car traffic, distinction between pleasure and commercial traffic, subdivision of commercial traffic into loaded and unloaded vehicles, weight per linear inch of tire of commercial traffic, number of horses drawing vehicle, weight and speed of motor cars and abnormal local traffic of extraordinary character Numerous highway supervisory bodies have drawn up forms which include the above important items more or less completely

The methods of securing traffic data are of extreme importance The methods where two extremes of time (one year and one month) are available for traffic census are discussed The following three methods applicable in both cases are considered (1) observations upon single days at regular intervals, (2) observations through a period of several consecutive days at intervals, (3) observations covering a period of three days, including Saturday and Sunday, at intervals The last-named method appears from the standpoint of economy of labor, probable clemency of weather (weather conditions at Providence, R I, considered in each case for a period of five years), and results obtained to be the most practical method for general use

The Present Status of the Relationship between Laboratory Tests and the Use of Road Materials W W CROSBY, Baltimore, Md

The science underlying the art of roadmaking is obtaining recognition For its development, laboratory tests and records of experience are necessary Some such have been available in the past, but these are, from their incompleteness, unsatisfactory now, especially as regards new materials and altered conditions of traffic By reference to the records and use of such tests as those for the resistance to abrasion of stone and the cementing qualities of the stone powder, is shown the value of such tests, and, at the same time, the incompleteness of the present knowledge More complete information is stated to be desirable as well as information along other lines, such for instance as the strength of stone under compression

The changes in traffic conditions, and the new records of the experience with both old and new materials under the changed conditions are referred to with some suggestions as to what definite information may be desirable

The statement is made that records from experience are needed, and not conclusions from assumed theories alone Also that the author believes it may be possible eventually to reduce many of the problems of highway engineering to a mathematical solution The beginning of the work of collecting information, and the desirability of cooperation are mentioned

Dr Octave Chanute and his Work in Engineering and Aeronautics JAMES MEANS, Boston, Mass

An appreciative review of the achievements of Dr Chanute (Published in full in SCIENCE)

Permanent Winds, their Causes and Directions. W J HUMPHREYS, Washington, D C

The temperature difference between tropical regions and those of higher latitudes establishes a barometric gradient from the warmer to the colder parts of the earth The resulting flow of the air together with the rotation of the earth causes the air of higher latitudes to flow from west to east, and that of the equatorial regions from east to west. The opposing centrifugal forces thus set up are the cause of belts of high pressure at latitudes 30° to 35° both north and south

These belts of high pressure are underrun at five places, two in the Pacific Ocean, two in the

Atlantic and one in the Indian, by cold ocean currents. Hence, each of these five places is the seat of a permanent high or anticyclone with its attendant permanent circular winds.

An Indicator for Determining the Efficiency of Aeroplanes or Kites: S. P. FERGUSON, Reno, Nev.

The author has devised a compact self recording instrument for indicating continuously the angle of incidence and lateral inclination of an aeroplane or kite together with the velocity, and the lateral and vertical oscillations in the direction of the wind with reference to the flying machine upon which it is carried. This instrument is based upon the kite meteorograph designed in 1905 by the author.

Determination of Altitudes of Aeroplanes by Triangulation: R. W. WILSON, Cambridge, Mass.

This paper contains an account of observations made by two methods to determine the maximum height reached by aeroplanes and a comparison of the results obtained at the Harvard Aviation Meet.

By one method observations were made with sextants in a fixed vertical plane which the aviator was to cross at his greatest altitude. Simultaneously observations were made by the other method in which theodolites were placed at the extremities of a base line three miles south of the field.

Technical Education in Aeronautics: C. H. PEABODY, Boston, Mass.

Technical education must eventually be offered for aeronautical engineers, the question is whether now is the time. The phases of this question are financial support, subject matter for instruction, method of securing teachers. The writer favors training a teacher for the purpose, and the establishment of undergraduate courses of instruction now. He offers a suggested course parallel to a course for naval architects.

A Program of Aeronautical Research Work, with Special Reference to what may be done at the Colleges: A. A. MERRILL, Boston, Mass.

In this paper the work suggests four general lines along which research could be profitably conducted: (1) the problem of construction, (2) the problem of efficiency, (3) the problem of power, (4) the problem of stability.

In connection with each problem the author pointed out just what research work is necessary and to what extent the colleges are fitted to undertake this work.

Some Experiments on the Pressure of a Current of Air on Certain Surfaces: G. LANZA, Boston, Mass.

The paper explains the need of an apparatus consisting of a blower, for the production of a current of air, and of a tube for directing this current against the surface to be experimented upon. Also the means of obtaining a current free from gusts, and having a uniform velocity at all points of the cross section of the tube.

Reasons are also given why the experimental surface should not be placed inside the tube, but should be located outside of and near its mouth.

The value of K in the formula $P = KV^2$ was found as a result of these experiments to be $K = 0.0031$, whence $P =$ pressure in pounds, and $V =$ velocity in miles per hour, the experimental surface being a plane surface one foot square placed at right angles to the current.

The results are also given which were obtained by an investigation of the vortex formed under the prow of a surface formed to approximate the underside of the wings of certain birds, and placed at small angles of inclination to the current. The need of a larger apparatus of the same kind is urged.

The Increase of Wind-pressure on a Normal Surface with Height: A. H. PALMER, Hyde Park, Mass.

The increase of wind pressure on a normal surface with increasing height is of considerable importance in aeronautical construction. From the known decrease of atmospheric pressure with height, and the wind velocity in the free air obtained by means of kites and observations of clouds at Blue Hill Observatory, the wind-pressure in pounds per square foot upon a vertical plane has been computed and has been plotted in a diagram.

Normal Stress and Resultant Pressure: A. F. ZAHM, Washington, D. C.

Extract from forthcoming book on "Aerodynamics" by Mr. Zahm.

Early Attempts to Navigate the Air: J. J. GREEN, Notre Dame, Ind.

Outline of history of aerial navigation from the time of Daedalus and Icarus through the middle ages down to the invention of the balloon. Scientific work done with the balloon. Its use by the postal authorities during the siege of Paris. Langley, Lilienthal, Chanute, Ader and their work, brief statements except in case of Ader's work.

THE BASIS AND OBJECT OF ARCHEOLOGICAL RESEARCH IN MEXICO AND ADJOINING COUNTRIES[1]

BY the mutual agreement between the government of Mexico and other governments and scientific societies of Europe and America, it has been decided to establish an International School of American Archeology and Ethnology in the City of Mexico, and as the honor of being the first director of the school has fallen to my share, I beg leave to place before this illustrious assembly the reasons which determined the patrons and protectors of the school to found it, and to dwell a little more fully on the ends that we hope to achieve in this new institution

We call our school the "International School of American Archeology and Ethnology," that is to say, we wish to treat two sciences, the importance of which is more and more clearly recognized in our day, and which are in reality sisters—for what we call archeology is but a branch of ethnology, from which it differs rather in method than in aim Archeology has reached its highest development and

[1] Inaugural address of the director at the opening of the International School of American Archeology and Ethnology in Mexico City on January 20 Porfirio Diaz, president of the Mexican republic, opened the school in the presence of the ministers of state and public instruction of the republic, of the ambassadors of countries that participate in the establishment of the school, and of many prominent citizens After the inaugural address by Professor Seler and an address by Señor Ezequiel A Chávez, subsecretary of public instruction, who dwelt on the importance of international cooperation in the establishment of the school, the president declared the school opened.

achieved its greatest triumphs in classical archeology and in the prehistoric archeology of Europe. For centuries the political and civil history of the Romans, Greeks and Oriental nations have been taught in the schools of the Old World. By the efforts of thousands of learned and industrious investigators, whatever knowledge could be obtained from descriptions and reports of historians, from the study of monuments that have survived the destruction of the old world, has been recorded and secured for the benefit of scientists and of the general public. We may say without exaggeration that an exact knowledge of the political and social life and of the characteristics of the individual life of the people of antiquity, a true concept of the extent of the influences arising therefrom, of the influences these civilizations received from the neighboring countries, and of the source from which they sprang,—was not attained until ancient history applied archeological methods, until by the use of the spade were unearthed the homes, graves, utensils, arms, ornaments, costumes, the remains of human bodies, and the worm-eaten literature of that ancient people.

Thus it was proved that field work was most necessary for the progress of archeology, underground lie the documents, truthful witnesses of the ancient civilizations about which we read, underground lie also the remains that are witnesses of civilizations, and the forms of primitive development of which no historian has written a single word. It is only necessary to bring them to light. However, for this kind of work, the energies of a single man are insufficient, no matter how skillful, diligent or learned he may be. Nor are the means sufficient which a scientist standing alone has at his disposal.

For these reasons in different countries of the European continent, the governments have taken upon themselves to establish and support institutions, to appoint directors and assistants who are charged with the task of exploring the centers of ancient civilizations, in the classic soil of Italy, Greece, Egypt, Babylonia, Assyria and other parts of the world. Associations of private citizens interested in this subject compete with the governments. In this way were organized the French, German, English and Austrian schools and those of the United States of America and other nations, in Rome, Athens, Smyrna, Cairo, Crete, Babylon, etc.

In establishing the institutions, the governments, scientists and scientific societies had a double purpose. The first and foremost was of course to learn as accurately and as completely as possible the characteristics of that great civilization whose heirs are we who live in Europe now, and which has spread to this continent and to other parts of the world. To accomplish this purpose it was important to preserve the relics that were found, to collect small objects and to note the places where they were discovered and the manner in which they had been deposited, and to keep them in museums.

The other object which the governments and scientific associations wished to attain was more particularly of an educational character. This purpose was partly accomplished by the museums, which were enriched by the finds made by archeological research. The peculiar traits as well as the artistic character of the remains that had been collected were admirably adapted to impress the imagination and to teach the young. There are, however, a great many things which can not be kept in museums, and there are many others which can only be seen and studied in the museums of the countries in which they have been found.

There are—most important of all—the people, the descendants of the ancient civilized nations, their countries, their skies, their climate, their whole environment, their way of living and the whole combination of imponderable agencies, the knowledge of which enables the student to understand the thousand peculiarities of the life and fate of the people. All of these and the particular methods of investigation were what was desired to teach the young in the schools of archeology that have been established with so much liberality in the classic countries of the Old World.

Work of this kind has been in operation for generations and with marked success. Whole cities arose anew from the accumulation of débris of thousands of years that had covered them, temples with rich ornamentation were restored, the secrets of the Egyptian pyramids, of the temples of Babylonia and Assyria, were brought to our view, together with countless objects, many of which were of inestimable value. These were preserved to delight the eye and satisfy the mind of mankind, and from them many students have learned to see, understand and work.

On the American continent, in the United States and in the Dominion of Canada, great interest was manifested in the ethnology of the Indian races and in its antiquities ever since the middle of the past century. Scientific associations and private parties rivalled in collecting data and documents, and the governments, aided by liberal means, undertook the direction of the investigation. Recently archeological investigations have also been instituted on a larger scale in South America in the Argentine Republic, particularly in the Andean region of that republic. Something has also been done in Brazil, Bolivia, Peru and Ecuador, by the cooperation of private parties, institutions of the United States and the governments of South America. Some foreigners have also worked in the republics of Central America, as well as in Yucatan and Chiapas: the Englishman Alfred P. Maudslay, the Frenchman Désiré Charney, the investigators of the Peabody Museum of Cambridge, Mass., the Germans Berendt and Teoberto Maler, the Swedes Bovallius and Hartman. Great additions to our knowledge of the ancient peoples of those regions were derived from their work. In Mexico the explorations authorized by the government in Xochicalco, Cempoallan, Monte Alban and Teotihuacan have contributed much to enlarge and deepen our knowledge. Magnificent monuments which were little known, and which were covered by débris or hidden by tropical vegetation, were unveiled. This work awakened more and more interest among the educated classes of other countries, and especially among our neighbors to the north. Thus arose the idea of cooperation, of the union of efforts, of the necessity of establishing a center to direct the work, at which the young student can learn, who, full of enthusiasm for those studies, might wish to come here to learn what books and the objects accumulated in museums could not teach him. This was the object and aim in founding a school of the same kind as existed in Rome, and with the same aims, but international in character. It is not necessary to enter into details to show the particular opportunities of such a school in this country, but we shall be grateful to those who initiated and fathered the idea, for the zeal and perseverance with which they worked to accomplish their end. We must be grateful particularly to the government of this republic, that owns this soil, and to the ministry of public instruction, whose solicitude for the study and preservation of all the archeological treasures of this country is

well known, and which with great kindness supported the project and lent it its efficient aid

Permit me now to set forth in a few words the tasks that this new institution will have to take up, and the way in which I think the work should proceed

The historian places the highest value on the testimony he can gather from living witnesses The descendants of the ancient peoples of this country, in so far as they still speak their old languages and observe their old customs, are in a way living witnesses, whose testimony is of value for the knowledge of ancient history, ancient political and social life The Indian of this country holds so tenaciously to his old customs, he is so devoted to the soil of his birth and that of his ancestors, that only by main force can he be taken from it

When we remember that since the time of the Conquest all hostilities and wars between the tribes have ceased, we may take it for granted that on the whole, and with few exceptions, the geographical distribution of tribes that exists to-day is the same as at the time of the Conquest, that is to say, that if a certain native language is now spoken in a certain place, we may assume until the contrary is proven that the same language was spoken there at the time of the Conquest For this reason it is of the greatest importance, not only for the ethnologist, but also for the historian and archeologist, to have an exact knowledge of the geographical distribution of the Indian languages spoken to-day, and for this reason I consider the preparation of a map that will give all the details of this distribution, as one of the labors that should occupy the attention of the International School of Archæology and Ethnology established to-day

The people who speak the same language do not necessarily form a homogeneous group, there are differences among them which correspond to the diversity of place and condition in which they live or lived, and to their history Such differences express themselves even in language, and for this reason the study of the dialects is also essential for historical investigation, and will form one of the tasks of the International School We are grateful to my distinguished colleague, Dr Boas, who offers his thorough knowledge and experience in this laborious enterprise

Another help in our investigation that may be of great value are the Indian people of to-day, in so far as they still retain the customs of their forefathers of the time of the Conquest, and in so far as they still retain the traditions, beliefs and tales, adulterated or not, which belonged to the time of paganism The folk-lore of the Indian tribes of this country will be another and very important part of the labors of our school

Lastly, we should not forget to study the industries and art of the Indian people, however much they may have been influenced, mixed and changed by the artistic style and the industries that the Spaniards brought with them, there remain in many places the survivals of ancient industry, designs and forms that remind us of ancient styles, that will be of value for purposes of comparison, and that may complete the history of ancient design and help us in its interpretation.

Archeology proper—that is to say, the ethnology of the races and peoples that no longer exist—has the same aims as ethnology, but its methods are much more limited. The archeologist can not collect at will from living people the elements of the language that was spoken, the traditions, the tales, the beliefs and all the evidence of mental development He must be satisfied with what writers of earlier times—

investigators, historians or general writers—considered worth while to note down. Nor can the archeologist investigate the entire cultural work of a race or people He can only depend upon the little that good fortune has saved from general destruction, caused by the violence of man, by his negligence and the destructive agencies of time, climate and vegetation The more is it important for the scientists to collect all the evidence, important as well as that of seeming insignificance, to keep account of the notes that refer to the evidence, to its origin, etc, and to utilize thoroughly the written documents, the descriptions of historians and of the contemporaries of those times, in order to obtain from these documents all possible help for the interpretation of the history of the people

Useful documents are not lacking in this country—that is, in the region with which historians have particularly occupied themselves—in this valley, in the environment of the capital and among the Tlatepotzcas (people that live beyond the mountains), in Cholula, Tlaxcala and its dependencies, the home of the nation or nations that were leaders in this country Beyond the limits of the central region, in the provinces, the reports and documents are very scarce There is no Sahagun for Michoacan and the northeast, nor for the Otomis, near neighbors of the Mexicans of the central region, nor for the gulf coast, nor for the great and rich provinces of the Zapotecas and Mixtecas; and the same is true of the region of the isthmus and the different parts of the people of the Maya family Regarding all these large provinces we have not more than scattered notes, and few incoherent accounts. Here archeology is the only means that can furnish the data, or any data necessary for the reconstruction of the history of these ancient people and the characteristics of their civilizations

The International School, in its archeological department, will, in the first place, study the monuments that are in existence and that are accessible, making comparisons and trying to interpret them by means of the old trustworthy accounts, and by means of what may be gleaned from the paintings, the contemporaries of pagan times, or of those made not long after the Conquest

The Maya monuments are a problem in themselves As this people had developed the art of writing to a higher degree than any other people on this continent, having originated very nearly a true hieroglyphic writing, and as at the same time they used these characters and signs frequently in their books as well as in their architecture, the Maya monuments should teach us more than those that are found in other parts Unfortunately, in that region an authoritative interpretation is lacking entirely Some of the characters have been deciphered, much more remains to be deciphered The International School will also apply its efforts to this important but difficult branch of the investigation.

The principal work with which the International School will occupy itself will be the search for new material, choosing appropriate places for which the authorities in whose charge the preservation of the monuments of the country is placed, will give the needed authority; discovering, measuring and studying what is found, looking for and bringing together detached pieces, taking photographs and drawings of entire monuments, of special details, opening burials and securing the contents for the museum of the nation.

The school will make efforts to fill in the fragmentary picture of our knowledge in order to give us a better idea of the differ-

ent civilizations that existed in this country—an idea that unfortunately the writers of earlier times did not give us

At the same time, we must not forget to study the cultural strata to see if there be in some place some means of arriving at a classification or chronological order in which the civilizations followed one another, a history that we have not been able to establish up to this day All these propositions will require the cooperation of the young who will learn and will in turn become our teachers, who will continue our work, disregarding and boldly setting aside the doubts and hesitancies of the old, and who will not fear to open new paths and with youthful vigor bring to a happy end what we have only been able to begin

EDUARD SELER

THE PLACE OF RESEARCH IN UNDERGRADUATE SCHOOLS[1]

THE aim of this academy is the encouragement of research along scientific lines by establishing and maintaining intercourse among those engaged therein, thus stimulating them by a consciousness of companionship in productive intellectual activity In a small society, embracing in its scope all the sciences, one does not expect in these days of specialization to find others engaged in just the same field of investigation as himself, it is through inspiration rather than information that the investigator profits by these meetings

It is now hardly necessary to emphasize, even to the non-scientific public, the importance of scientific research, to it mankind owes in a large measure not only his material prosperity, comforts and conveniences, which is sufficiently obvious, but, what is even more important, his intellectual freedom. The changes that have taken place within the last century in our physical environment, with the innumerable applications of science to useful purposes, are no more profound than our intellectual advance and the growing pervasiveness of the scientific spirit in all lines of thought and endeavor for human betterment, physical, social and moral. Our increasingly extensive and effective philanthropies, our giant strides in sanitary administration, and the tottering barriers between the sects of Christendom, are very tangible evidences of the spirit that is not satisfied with precedent or authority, but craves certainty as to the facts, and reasonable explanations for them, as well as the application of all knowledge to the uses of man

The membership of this academy happily includes scientific workers in many fields Some apply the results of research to the needs of the state in developing its resources and protecting its citizens against the injuries inflicted by ignorance and fraud, others make science the servant of industry and commerce, others, again, are active in applying it to the preserving and restoring of the health of our bodies A large part of our membership, however, is made up of those whose chief occupation is teaching

While it has not always been the case, it is probably true at present that the most valuable contributions to human knowledge are made by those engaged in this profession of teaching This is not surprising, for the nature of his calling demands that the teacher to be effective must ever continue to be a student, and the thorough study of any subject reveals the limits of our knowledge in that field and tempts the man of active intellect to the task of extending those boundaries; there is surely no keener pleasure than the learning by one's own search some truth, however inconspicuous, not previously known.

[1] Address of the president of the Indiana Academy of Science, November 25, 1910.

Not only does teaching tend to stimulate research, it also gives it balance by preventing the too exclusive attention to the comparatively narrow field under intensive cultivation, the necessity of presenting well-ordered information covering the broader subject, and the oral statement of original theories and conclusions, must have a broadening and clarifying influence on the intellectual activity of the investigator

As teaching is a help to research, still more is research a vitalizer of teaching, particularly of the teaching appropriate for graduate students, indeed, the work of research is at least as important as that of instruction where advanced students are concerned, and the university should be a source of new knowledge, where those desiring to devote themselves to the same high quest may be stimulated by the example and companionship of productive scholars

The leading European nations have apparently realized more clearly than we the value of scientific research, and have provided more adequate rewards and more favorable environment for the investigator, with the result that the ratio of intellectual to material prosperity is higher there than here Within the past generation, however, we have become more awake to these matters, and have determined in our strenuous way to make research "hum" The awakening has unquestionably been beneficial on the whole, but we have, it seems to me, failed to grasp certain fundamental distinctions between the needs of graduate and of undergraduate students, the hum of research has been allowed to drown the cries of the injured in many an undergraduate school, where teaching is sacrificed to research, and where too early specialization is encouraged and even forced upon the student.

We are not as yet in this country producing our proper share of scholars of the first rank The reasons for this are many, including hasty preparation, premature specialization, insufficient rewards, and unfavorable environment

As to preparation, those of us who contemplate academic careers are usually unwilling to invest sufficient capital of time and money, we expect to complete our scholastic education, if uninterrupted, at about twenty-five years of age and then enter upon an active career in which there is little time or opportunity for research or even very serious or intensive study, for the sake of the immediate pecuniary reward, in Europe, several more years are spent in subordinate positions as investigators, on a semi-independent basis both scholastically and financially The European makes a larger investment and reaps a larger ultimate reward, not only in money, but still more in the consideration accorded to intellectual eminence

Concerning too early specialization and its shallow results, I shall speak later, let it suffice here to say that, for example, he is a poor chemist who is only a chemist

The rewards at present offered for pure scientific work in this country are insufficient to attract the most vigorous, capable and ambitious men, not only, nor chiefly, are the financial returns here less than in Europe in spite of our higher cost of living, but the public respect for intellectual distinction is far inferior in this country, on account of our commercialism and our acceptance of wealth as our standard evidence of merit

The environment, too, is less favorable to the highest scientific work in that the numbers of those engaged therein are so few, and the national characteristic of haste rather than thoroughness pervades our activity. The value of real scientific

attainment is still but dimly recognized by the industrial world, chemists are employed like clerks, without graduate training, and work like day-laborers, but for less pay, at routine analysis, with neither the training nor the opportunity to attack the larger problems in a fundamental scientific way Such chemists are not on the same plane as the higher chemists in the German manufacturing industries, who have supervision of the works as well as the laboratories One result of this primitive lack of demand for highly trained men is the small number pursuing research in our universities, so that even our best qualified professors have a mere handful of research students, and many of these can be induced to continue their higher education only by fellowships sufficient to pay their living expenses, if such aids were discontinued the numbers of our graduate students would be even less favorably impressive than at present, though in time the larger investment of those remaining would show in the larger salaries that would have to be paid to the men more difficult to find Leading German professors attract large numbers of well-trained students, making possible their remarkable productiveness.

The keener competition in all walks of life in Europe has some advantages—only the thoroughly trained can hope for success, hence their desire for the most complete preparation. We consider ourselves fortunate in being protected against foreign competition, and in being able in consequence to make an equally good living with less effort, but are we really to be congratulated on our lower intellectual standard of living and on our dependence upon imported thought and intellectual products?

Another result of the limited scale on which scientific investigation is being conducted, and our "high standard of living," is that it is not worth while for manufacturers here to supply refined or unusual scientific material, if an American investigator needs, for instance, a special chemical, he must wait two or three months for its importation, while his European colleague could obtain the same in as many days or even hours, or, if manufactured here, two or three times the foreign price must be paid The American artisan is more highly paid than his European brother, but not so the more eminent intellectual worker. Does this mean that we are not civilized enough to appreciate any but material products?

Naturally the realization of the value of intellectual things is found first among those engaged in the work of education, and our larger and better endowed colleges have within the last half century shown their appreciation of productive scholarship and developed graduate schools to compare more favorably with the European universities, so that it is no longer necessary for our students to go abroad for the inspiration of working with men who are extending the boundaries of human knowledge Once started, the fascination of research insures its continuance as long as a favorable environment exists.

The institutions that have been able by their large means to adequately maintain graduate departments have been so amply rewarded by their enhanced prestige, that many others, without sufficient means, have attempted to do the same thing; the result has been impaired undergraduate instruction with a more or less successful imitation of graduate work.

A graduate school should recognize as its most important possession the productive scholarship of its faculty, making the institution a center of new knowledge, and all other matters should be arranged with

a view to encourage and stimulate scientific investigation. A very moderate amount of class instruction and other duties should be demanded of the members of the faculty, and students should be sufficiently mature and earnest to work without compulsion and with little direction under the guidance and inspiration of the men who are doing real original work

The case of the undergraduate school is fundamentally different I believe that the prominence given to research in many undergraduate schools is a positive injury to the student; his instructors are chosen on account of their ability or promise as investigators instead of their qualifications as teachers, and even the student himself is encouraged or forced to undertake so-called research with entirely inadequate training, both as regards breadth and depth The undergraduate years should be employed in acquiring a well-balanced knowledge of the fundamentals of the student's specialty, and an acquaintance with the elements of many allied subjects, together with a working grasp of such tools as modern languages, to make professional literature accessible at first hand, mathematics, for the mental training and grasp of the quantitative and statistical treatment of all studies, and every undergraduate student should give such attention to history, literature, and economics as to make him an intelligent citizen and man of culture.

Only when this has been in a measure accomplished—and in looking back to our own college days we realize that a mere beginning had been made when we graduated—is the student in a position to profitably undertake research with a proper appreciation of what he is doing and how to do it, so that it is really research for him and he is not merely a pair of hands under the direction of another's brain. The effectiveness of a scientific investigator is generally proportional to the thoroughness of his preparation, too many attempt to discover new truths before they have grasped those already discovered by others

In many institutions one of the requirements for graduation is called a thesis, and such a tradition is difficult to dislodge, but I think the name is unfortunately pretentious and is apt to mislead the student into thinking himself more advanced than the facts justify, it savors of the same spirit that induces the high school to ape the college in so many ways, in its pernicious fraternities and even in having a "baccalaureate" service—doubtless to celebrate the fact that the boys about to graduate are still unmarried, such unwholesome symptoms are usually most conspicuous in institutions with the least merit. The preparation of an undergraduate thesis may be a valuable item in the course if it is not so administered as to waste the student's time, narrow his mind and swell his head I believe its most valuable feature is its compelling him to go to original sources for information, namely, library work Too many students graduate without this experience and with a knowledge of books limited to the prescribed texts employed in the course. To choose a subject of real interest to the student and of suitably narrow scope, and to find out by systematic search in the scientific journals all that is known about it, and then to write an essay in which the information is carefully arranged and well presented, is a task well worth the performance.

It is entirely laudable for every institution to aim at ever higher goals, not, however, by raising the entrance requirements beyond the reach of its natural constituent, even at the dictation of some self-appointed board demanding uniformity under diverse conditions, and not by

changing the object of its training—there would not be necessarily any gain to the community at large should a school of pharmacy gradually become a theological seminary or even a medical college, a school of pharmacy is just as necessary as either of the others

It is perfectly natural for any teacher or group of teachers to aspire to more advanced grades of work, but this should not be undertaken unless the more elementary and fundamental work is adequately cared for

We are suffering from too much ambition of this kind, too many trade schools attempt to be colleges, and too many colleges attempt to be universities, at the expense of their efficiency in their original equally important field Let us imagine that every grade school gradually introduced more and more work of the high school, that every high school gradually became a college, and that every college gave more and more of its energies to graduate students! Or let us imagine that every institution giving grammar school instruction attempted also to provide training through the high school, college and university curriculum! What a ridiculous and inefficient educational system must result Roughly speaking, for every thousand grade schools we need about a hundred high schools, ten colleges and technical schools, and one graduate university

Fortunately, there is a supervision that prevents the transformation of grade schools into high schools, and separates the work of the two as soon as numbers of pupils justify the step, it is a pity that there is no authority with power to insure similar efficiency on the part of undergraduate and graduate colleges and universities

We are failing to appreciate the distinction between undergraduate and graduate work In most ways there is little more in common between these than between that of the high school and of the college, and the university is injured in the attempt to make it a small part of a large college Efforts have been made in this country to have universities unhampered by undergraduate departments, unfortunately, however, the country has declared itself not yet ready for such a logical and much-to-be-desired arrangement

The chief function of the undergraduate school is to give instruction in such a way as to insure mental development For those few who are to proceed to graduate work, the soundness, breadth and depth of the foundation will largely determine the safety and usefulness of the superstructure of specialization to be erected later The first qualification for membership in the teaching staff of an undergraduate school should be teaching ability together with a thorough knowledge of the subject to be taught

This teaching ability is largely a natural gift, and if of a high order is not common. Let us recognize it, use it, and reward it as an asset of the highest value It can not be created by the study of pedagogy any more than logical thinking by the study of logic, it is founded on the intuition of sympathy Teaching is the keenest pleasure to some, the hardest drudgery to others; the student readily distinguishes the two. I would not, however, imply that even the best teacher can work effectively with the undergraduate who struggles to escape education or who is unwilling to make any effort for it because his interests are now intellectual, such students have no proper place in an institution of higher learning, and we expend much too large a part of our energy in forcing such material through to graduation The fashionableness of going to college is by no means an unmixed blessing Why does not some en-

terprising individual start a college with luxurious dormitories and means of recreation and dissipation, where work shall be optional and house-parties continuous? Enormous fees could be charged, professional athletes employed, a suitable degree conferred after four years, and the working colleges protected from young men not desiring to be educated.

The chief function of an undergraduate institution is instruction, and its faculty should be chosen with this in view. Every such teacher, however, to attain his highest efficiency, should engage in some kind of research, that is, getting new information at first hand. This can not fail to have a vitalizing effect on his teaching, keeping clear the distinction between fact and theory, and maintaining his instruction abreast of the times.

There is questioning of the value of much that is published as scientific research, and it is easy to criticize the spirit that piles up undigested data or adds to the number of chemical compounds for the sake of having something to publish; it is impossible to say, however, that any such information is and will continue to be valueless. I am less interested in discrediting such work because it now receives higher recognition from the undiscriminating in the educational world than it deserves, than I am in asking for recognition for a kind of labor, just as truly research, that now receives too scant credit from the public and from those responsible for the distribution of rewards to college teachers. I refer to what may be called pedagogical research—the labor involved in improving and constantly rejuvenating the instructional work. Any course that remains unchanged for many years is probably in need of repairs, but desirable changes usually involve much labor on the part of the instructor. The teacher whose heart is in his teaching and who carries the usual overload of duties is likely to be kept busy at just such work, and have no time left for the more conventional kinds of research, but his students will profit by his labors. The administrative officer who directly or indirectly puts pressure upon a college teacher to neglect his teaching is seriously injuring the college, yet this is by no means uncommon, intentionally or otherwise.

Research, of whatever kind, is largely a matter of inspiration, and can not be forced; as profitably might a poet be urged to become a painter as a scholar be pressed to undertake investigations foreign to his inspiration. Left to himself, the investigator will do what he is most interested in and therefore likely to do most fruitfully; to attempt to force a teacher whose instincts are for pedagogical research to other kinds of investigation is likely to spoil a good teacher and make a mediocre investigator. The method of forcing commonly practised is the indirect but very effectual one of recognition of published research by promotion and increased remuneration, while devotion to teaching and pedagogical research receive no such rewards.

Let us recall our own undergraduate experiences. Did we not in many cases get most stimulation and make most progress under teachers unknown in the professional journals? It is to be expected, indeed, that the teacher whose chief pride and interest are in his teaching, and whose chief reward is the advancement of his students, should be of more real value to those students than the investigator whose hours of reflection are devoted to the problems of his research, and to whom the instruction of classes is incidental, if not, as in many cases, an unwelcome interruption. Gifts of an equally high order for instruction

and for investigation are not usually found in the same individual, let each give his main effort to what he can do best, let the investigator work with mature students and the teacher with the immature, and let the distributors of rewards make no invidious distinctions in the recognition of the two equally necessary and meritorious services.

It is eminently desirable that a teacher should be also an investigator; in every faculty, however, some members have more pronounced ability than others in this direction, and it is proper that such should receive special consideration as to other demands upon their time and attention in order to enhance their productiveness by favorable conditions. To the others, whose bent is less marked in the direction of research, should be assigned the duties of administration and the committee work, with, if necessary, the high school commencement addresses. Neither should the more general business of the college be regarded as of any less value or importance than research, or less worthy of reward. To be sure, it has not the same advertising value, but an institution of learning should be above adopting the motto "quick returns and small profits." The most enduring good accrues to the students, and therefore to the college, from inspired teaching and wise and careful administration.

It is certainly the part of wisdom to provide as favorable conditions as circumstances will permit for the encouragement of research. Several factors more or less obvious enter into this favorable environment and influence the productiveness of the investigator, but the real determining factor is in the man himself; he must have ideas, enthusiasm and industry, he may even be a crank, he must have an accurate memory to retain the results of extensive reading, and as much as any one can profit by good health, to withstand the strain of concentrated and continuous effort; he must be absolutely honest with himself and the professional world. If he has the necessary qualities it is very unfortunate if his circumstances do not permit their most fruitful activity, if he has not, let him serve his institution in other ways for which he is better fitted—ways of equal importance. Few men can spend several hours daily with classes, several more in administrative work, one or two more in committees, and have any vitality left either for research or professional growth.

The greatest need of most successful college teachers is more time to think. The evil effects of the prevalent rush become apparent only very slowly—in the course of years—in a gradually failing effectiveness for lack of mental nourishment. No one can use a few minutes now and then, snatched from the more urgent duties of the moment, to do or even think real research, ideas do not come on demand, interruptions are often fatal to inspiration, experimental work often must be continuous to lead to results, investigation that is worth while is not a routine operation to be started and stopped by a gong; there must be mental growth as a background. It would probably be economical in the long run if the real teacher-investigator could be assured of uninterrupted privacy for half of every day.

In addition to time for thought, reading, experimentation and writing, the teacher of science needs space and material equipment. There is a temptation to spend money most freely in ways that lead to the most tangible results, and would-be benefactors may cause serious embarrassment by providing buildings without equipment or endowment; blessed be the liberal contributors to the "gen-

eral fund," meaning equipment and, most important of all, competent men

In the providing of suitable buildings with limited means, circumstances must decide how much can be devoted to what may be called luxuries and quality as against necessities and quantity, it is certainly desirable to have buildings as beautiful as possible, but not at the expense of adequate size and equipment

Books are too often a crying need, they cost so much and they show so little; and yet without them research is impossible The most serious lack is usually that of complete files of the scientific journals, which can *never* be purchased on a non-accumulating allowance of a hundred dollars a year The value of the library habit to the student can hardly be overestimated, but to develop this plenty of books and an attractive place for reading them are almost indispensable How welcome to the business manager of many a college in straitened circumstances would be the professor who "did not read books but wrote them"

Turning now to the question of assistance, from the purely business standpoint, a man should not be required to do what a cheaper man can do as well; the problem, however, is by no means solved by so stating it The profitable use of assistants is a far from simple matter, their duties should be so assigned and supervised that their time may be spent to the advantage of the department and also to their own obvious profit The men available have usually recently graduated and should realize that the salary is not the chief reward for their services, but that the time spent as an assistant in a well-conducted department is valuable as a period of education and necessarily precedes any more advanced position in the college or university world. The assistant should welcome all such experience, even if some drudgery is included, as gives him an insight into the teaching of his subject and the management of departmental business, such as the handling and ordering of supplies, the administration of classes, and the keeping of systematic records To really review and extend his knowledge of the fundamentals of his subject so as to meet the needs of students entitled to his help is no slight task, but the assistant should use his utmost efforts towards progress in more advanced study and in research if his preparation is adequate The assistant who shows the right qualities will not long fail to receive recognition and promotion; in the teacher's profession "everything comes to him as can wait" as far as he has the qualifications Given the natural ability, industry and personality, thorough preparation will compel success, an assistant's position in a large and efficient department in association with successful men is better preparation for ultimate success in college or university work than the better paid positions in high schools open to men of equal training

Those having charge of assistants should see to it that there is opportunity and encouragement for proper growth It is through such assistants that the older teachers may hope to accomplish research, in doing which both are equally benefited It is, however, something of a deception to call such assistants' positions "fellowships" if the duties of the department occupy any considerable part of the time

It is certainly desirable that the more experienced teacher should delegate to assistants such of his work as can be properly done by them, it is very undesirable that he should cease to have direct and constant contact with the work of students, the direction and development of courses should remain actually in his

hands and the work of assistants be under constant scrutiny. When it becomes impossible for a course to continue actually under the direct management of a senior instructor it should be placed in charge of a qualified associate whose responsibility will be the incentive for his best work, the plan followed in some universities of having courses nominally in the hands of those for whom it is impossible to actually direct the work, which is really done by junior men, is essentially unfair to the latter, in withholding from them the credit to which they are entitled, not conducive to the best results in that it fails to provide the incentive for devoted effort on the part of those actually planning and administering the work, and an imposition on the college and the public, who believe the courses to be really administered by the more widely known teacher. Many a student has been disappointed in finding that he has little or no contact with the man advertised as having the work in charge.

In growing institutions it is the usual experience of the teacher that other duties encroach more and more upon his instruction and research, the latter being first sacrificed. Some of these are indispensable, such as the keeping of accurate records of students' work, and as institution and department grow there is some unavoidable increase in the machinery for handling students, the red tape and machinery should be recognized as a necessary evil—a means not an end—and kept at a minimum, if the choice were imposed between good teaching with no records and good records with no teaching, the election would be simple. There may be a conflict of opinion on this subject, however, between the engineer of the beautiful machine and the poor laborer whose energies are consumed in feeding it with reports. I believe that we devote too large a part of our attention to the lazy and incompetent, to the detriment of the more energetic and able students, on account of the struggle for the prestige accorded to numbers, which we may also charge with the use of colleges as lounging places for the sport and the intellectual dead-beat. It is surely unfortunate if a teacher has to spend his time in keeping elaborate records of and forcing the loafers instead of stimulating and satisfying the gifted.

The question of salary has an intimate bearing upon the efficiency of college teachers, and it is generally admitted that they are underpaid. The cost of living varies so widely in different college towns that a salary adequate in one would be entirely insufficient in another, so that it is impossible to name a suitable salary. As a general principle, however, it may be accepted that the remuneration should be enough to attract men of energy and ability and make possible their best work. It is not desirable that teachers should vie with the commercial classes in display or in expensive amusements, and men of intellectual strength would not wish to, it is proper that they should receive enough to permit comfort without anxiety, membership in scientific societies and the opportunity to attend their meetings, books and other professional tools, and also travel, society, and the enjoyment of music and art, for the sake of their own broad development and consequent influence in society as well as with their students. The man who never sees anything but his home and his place of business is certain to be narrow. Many young men ruin their professional prospects by marrying on a very small income even before their education is complete; it is no evidence of a lack of sentiment for a man to postpone marriage until he is in a position to properly main-

tain a family. Further, it is surely the cause or the result of second-rate qualifications as a college teacher to attempt to carry on another business with no bearing upon his professional pursuits for the sake of the increased income. Scarcely less valuable is the semi-professional routine of tutoring, commercial analysis, and even the preparation of uninspired text-books, for the same reason. These things do not give the best preparation for and naturally do not lead to the highest university positions, though they do bring immediate financial reward; better far devote the time to some research if there is any in the teacher, and qualify for advancement in the college or university world. In education as in business, both the teacher and the institution may expect to get what has been paid for; if the teacher gives less than his best efforts he may look for less than a full reward, and the institution that seeks bargains in teachers will probably get something cheap—and nasty; if first-rate results are to be achieved the price of first-rate ability must be paid, allowing for a long and expensive preparation.

The bearing of this upon the question of research is evident; to cultivate the vitality of the intellect it must be free—free from anxieties as to the necessities of life, free to proceed in broad and deep channels, with all the incentives of intercourse with things intellectual and esthetic.

The story is told of a college teacher, who was conspicuous at prayer meetings, that it was his custom in closing a lengthy petition covering a large amount of detail to say, "And now, O Lord, to recapitulate," and so on.

Permit me, then, in conclusion to summarize the points I have tried to present. In undergraduate schools research has a very important place as a stimulator and vitalizer of the teaching; it is, however, a secondary calling and should not be allowed to interfere with the main function of the undergraduate teacher, namely, instruction. The selection of men for such positions should be based primarily on their qualifications as teachers, and research should not be undertaken until a broad and deep foundation has been laid. The value of research, however, makes it most important that men capable of doing it should be helped in their efforts by the most favorable environment possible.

Lafayette, Indiana

A PLEA FOR ORGANIZED RESEARCH IN THE TROPICS

As science progresses we begin to look for new fields of research, for an increased sphere of investigation, for a greater and more varied amount of facts upon which to base our generalizations and our conclusions. As modern development generally becomes more pronounced we begin to reach out for opportunities in new regions, in those parts of the world where civilization has not yet gained a final foothold. To-day the tropical countries are still comparatively unknown, forming a terra incognita which contains many secrets for the explorer, many problems to be solved by the scientist, many riches to be gathered by the pioneers, always ready to exploit the resources of new regions.

With the striking diversity in their natural productions, their variety of geological structure, and their extreme conditions of climate, the tropics offer, in most branches of natural science, exceptional opportunities and wide fields for investigation and research.

Scientific research in the tropics has been carried on in a more or less perfunctory manner. Tropical research generally has not been conducted in a really scientific way. There is no organized and systematic investigation of tropical conditions, with the exception of a few years' work in this direction in Java and the Philippines.

I hasten to explain the above statements which at first sight may appear too sweeping and too severe It is true that by individual and public effort, in the eastern tropics, in India, Ceylon, Malaya, Java and the Philippines a large amount of scientific research on tropical subjects has been accomplished from time to time. Vast quantities of valuable observation have been accumulated, but we still lack scientific data from many other parts, without which we can not arrive at definite conclusions It is equally true that many individual scientists and scientific explorations have penetrated the swampy forests of the Amazon and the Orinoco, have marched over the pampas of Brazil and the llanos of Peru, have paddled up the affluents of Magdalena and Marañon rivers, climbed the snowy peaks of the Andes under a tropical sun, dwelt on the fever-infested sands of the Mosquito coast or sweltered in the dampness on the slopes of the Central American volcanoes, but all this work has been accomplished without a comprehensive plan or a definite purpose in view as to a final understanding of the conditions of the tropics. This pioneer work is most valuable, it has shown us what a marvelously rich field for research is to be found in the tropics.

The old European nations with tropical dependencies realized long ago that the successful opening up of their colonies depended on a proper knowledge of their resources. From the time of Linnæus, who sent many of his pupils to tropical countries, to that of the Honorable East India Company, from the time of Captain Cook's first voyage, when Banks and Solander gathered such valuable data, up to the present day the collections from the tropics have been mainly of an economic nature. These collections have been stored and studied in European and American scientific institutions, generally by scientific men who have not themselves had the opportunity of travelling in the tropics. Where such studies have been made on living specimens the latter have been kept under artificial conditions, which seldom if ever give a true imitation of the real natural surroundings such as they exist in the tropics.

The most important among such institutions in Europe is Kew, with its gardens, hothouses, museums and herbarium. By being the central place of tropical botanical research for the British colonies, as well as a school of tropical horticulture, which has produced a great number of scientific men for Great Britain's tropical dependencies, Kew has rendered tropical science invaluable service.

The Imperial Institute in London, in later years, has commenced to investigate colonial products more closely than was possible at Kew, and the brief but useful work of the Liverpool Institute for commercial research in the tropics indicated the lines upon which tropical investigation ought to be conducted The Liverpool School of Tropical Medicine through the investigations of Ross and others deserves the highest praise.

We find in India numerous scientific institutions for tropical research, and in the British colonies generally the botanical and acclimatization gardens have become features of the greatest importance Of British tropical gardens in the East, those in Singapore, Peradeniya, Calcutta and Kamerunga are especially noteworthy for their services to botanical science in general and to tropical agriculture in particular. The German, Brandis, organized Indian forestry on a scientific basis, which is not surpassed even by the work of Pinchot in this country, and the investigations in recent years at the Dehra Dun Forest Research Institute are unique in their thoroughness and value. It took an American to establish Indian agricultural research on a modern footing, and the Agricultural Research Institute at Pusa is now recognized as one of the leading institutions in the east.

The small acclimatization gardens in Brisbane, Port Darwin, Perak and Bangalore have been very useful in their way.

Holland found that the material progress of its colonies depended on the scientific development of agriculture, forestry, mining and other industries. With characteristic

thoroughness the Dutch set about the study of their colonial resources. The botanic garden at Buitenzorg with its many accessory institutions remains easily the leading one in the world, and the monumental work of Treub, whose recent death is a great loss, as an organizer and scientist can not be overestimated. His agricultural department of the Dutch East Indies was probably more efficient than any similar institution in the entire world.

The new development of the black continent has led to increased activity in the investigation of its scientific problems. Many new institutions of research have been founded, both in British, German, French, Belgian and Portuguese colonies in tropical Africa.

While the eastern tropics and their resources are comparatively well known, we have a very scant knowledge of the tropics of the western hemisphere.

Besides the few scientific institutions in the British and Dutch West Indies, and in Brazil, there are no botanical gardens, no agricultural experiment stations, no meteorological observatories, no medical research institutes, no zoological laboratories in the American tropics. In all the large territory of Central America, in Colombia, Venezuela, Ecuador and Peru there is absolutely nothing being done in scientific research of the tropics.

The United States of America have in recent years acquired valuable tropical dependencies, and in Porto Rico, Hawaii and the Philippines, notably in the last, scientific investigation is receiving due attention, in accordance with the requirements for scientific knowledge characteristic of present-day America.

The people of this country are, however, interested also in other parts of the American tropics, even if these are not political dependencies of the United States. It is sufficient to recall the fact that over a billion dollars of American money are invested in the tropics, in order to realize this. The American people investing in the tropical industries of the equatorial regions of this hemisphere have not had the assistance of science in making their investments secure and profitable. How different are conditions in Great Britain! America has been so preoccupied with the development of its own enormous resources that the tropical parts of this hemisphere have been left to work out their own destiny unaided.

The Monroe Doctrine as an expression of the homogeneity of all interests affecting America should cease to be a political theory only, and should be brought down to commercial, industrial, literary and scientific reciprocity between the American countries. Trade relations are becoming more intimate. It is time that scientific relations become more frequent.

Tropical America is to-day more European than American. For centuries maritime Europe has been trading with the American tropics, supplying immense amounts of capital for the development of their vast resources, and converting these countries into commercial, if not political, dependencies.

To this day Europe has done more for the scientific exploration of tropical America than American scientists. There is, fortunately, no Monroe Doctrine as regards American science. But thoughtful Americans can not but lament their country's neglect of the great opportunities for contributing to the progress of civilization in tropical America.

Every country in the world needs the products of the tropics. Those that have not tropical dependencies of their own must acquire such products from other countries. The requirements of a prosperous nation of 90,000,000 of consumers have created a great market for tropical products in the United States. Humanity in general derives to-day many products from tropical countries, which have become articles of daily need where a century ago they were luxuries.

Tropical America, with its vast areas of fertile land, its abundant rainfall and perfect climate, and its proximity to the world's largest market, is capable of supplying all the products of the tropics in enormous quantities.

To be able to take advantage of these conditions, it is of the greatest practical importance that we arrive at a better and proper understanding of tropical countries.

The aid of science is necessary to make the tropics habitable and productive. Academic as well as applied science has in the tropics an open field But we need organization and systematic work, instead of haphazard skimming of the surface of the scientific treasures of the tropics

Where the problems are legion, and where the material is as abundant, and the opportunities as frequent as they are in the tropics, it is a general failing of the scientific worker that he becomes interested in too many features to be able to do his best. This must be avoided

With the exception of the botanic gardens at Buitenzorg there are no scientific institutions in the tropics adequately equipped or properly manned The usual small institution with a staff of two or three scientific men, often hampered by demands on their time for work in applied science, can accomplish but little The need of a large institution for the investigation of tropical America becomes apparent when we take into consideration a few of the scientific and practical problems, which in thousands are waiting to be solved in the tropics.

The riches of tropical countries were the incentive which led to the great discoveries of unknown lands They furnished the principal motive for the travels and discoveries of Columbus, of Balboa, of Vasco di Gama, of Dampier and Captain Cook, of Bougainville Humboldt made his most acute observations while following the Cordillera through the American tropics Darwin and Wallace collected their most important evidence in tropical countries for the theory of natural selection Huxley, and Agassiz, father and son, acknowledged the value of their tropical journeys for their work

The educational value to the young naturalist of tropical travel is now well recognized It is to be hoped that an American institution for tropical research will make it possible for every young scientist of this great country to study for some time at least the peculiar conditions of the tropics and to contribute to the knowledge of tropical phenomena, by travel and investigation

The conditions of life in the tropics as far as prevailing external conditions are concerned, are favorable to the development of a multitude of individuals, and consequently there is such a severe struggle for existence as is entirely unknown in more temperate climates The many problems arising from this fact can not be studied to better advantage elsewhere.

There is no better place for a study of plant geographical problems than in the undisturbed regions of the tropics

Systematic observations of the phenological stages and similar features of tropical plants in their natural surroundings have yet to be undertaken

Very little work on the ecology of tropical plants has so far been done This should be undertaken in the tropics The hothouse method of studying plant phenomena is not reliable. Instead of showing the development of the tropical plant in its natural surroundings, it rather indicates the adaptability of the plant to unusual conditions and the possibility of acclimatization The plants can not be placed under natural conditions in artificial temperatures.

The plant pathologists will find the tropics teeming with lower forms of life preying upon vegetation, and work on these lines is in great demand and of immense practical value

The relation of plant life to geological conditions, the work of plants in changing the topography of the earth's surface, are equally interesting to the botanist and the geologist, and very little is so far known upon these questions from the tropics

While in cold regions there is a retardation of development of plant life caused by low temperatures, in the tropics the same effect is caused by variation in moisture. The latter factor controls plant life in tropical regions, while in temperate portions of the earth heat is the principal factor influencing vegetable phenomena. Thus the dry season in the tropics corresponds to the winter in other parts, it is the time of rest and death. These relations are as yet but little understood in the tropics

While light and the incident sunshine fur-

nish the mechanical or molecular energy at the disposition of the plant, they are the least understood of the climatic elements. In the tropics the light conditions are very intense and for this reason actinometric studies are especially necessary in tropical countries.

As for the chemical intensity of light, such comparative work as that of Roscoe and Thorpe in England, Portugal and Brazil opens up most interesting vistas of research.

While we have valuable results from temperate climates in regard to the relation of plants to soil moisture, evaporation and associated phenomena, we know practically nothing about these conditions in the tropics.

We know that in the tropics the average annual temperature differs but little, while the quantity of precipitation differs largely. The latter feature is of greater importance and needs therefore special study. We have a large amount of scattered data and much generalization, but practically nothing of definite scientific or practical value.

Tropical soils are as yet very little studied, except in a few localities, as in the West Indies, British Guiana and Java. The rapid decomposition of rock caused by the combination of abundant moisture and heat furnishes new layers of soil as well as a fascinating subject of study for the geologist and the chemist.

The numerous vegetable products of the American tropics are as yet very little known from a scientific point of view. There are scores of tan barks, dozens of oil-producing plants. New rubber plants are found frequently in the neotropical regions. New and old tropical fruits invite study, and economic plants generally occur in abundance.

When we consider that tropical America has given mankind more economic plants than any other part of the world, it seems strange that, after all, tropical America is less known to-day than any other region of the earth. We may only mention corn, potatoes, cacao, tobacco, rubber, sisal hemp, vanilla and probably bananas among the important vegetable products of the western hemisphere.

There is an open and very profitable field for the plant breeder in improving tropical products.

The tropics are inhabited by peculiar and interesting races of mankind, and traces of ancient civilizations are now obliterated by a luxuriant forest vegetation, which clothes the tropical lands from the level of the sea to the summits of the loftiest mountains. The anthropologist and the ethnologist find in tropical America some of the most complicated and interesting problems of research.

It is in the tropics where the principal volcanic belts encircle the globe, and with their variety of geological structure, their frequent earthquakes, their coral formations bathed by the tepid waters of the great tropical oceans, the tropics of America offer unequaled opportunities for geological studies.

The violent electric discharges in the tropics produce atmospheric nitrogen, which probably is carried by the rain water into the soil, and thus contributes to and probably explains some of the fertility of the tropical soils. Our knowledge in this regard is very limited.

Where the tropics teem with vegetable products of the most striking diversity, animal life also is most abundant and of great variety. Tropical zoology is so far only touched on the surface, and especially are the lower forms of animal life in the equatorial zone known only slightly.

The pathogenic bacteria have only in a few instances been investigated and a large field is here open. There has been much progress in tropical medicine during late years, but while we know the elements of this science there is still much to learn, many tropical diseases to study and many remedies to discover.

Modern science has demonstrated that life in the tropics is possible for white man, and if ordinary precautions are taken he is as safe there as in any other place. Tropical exploration has craved its dues in form of many martyrs to science, but with modern appliances and present-day knowledge there is no need of privations and exposure during tropical travels.

In this regard it is of special importance that systematic research in the tropics be

inaugurated, so that scientific workers may receive proper instructions and advice as to methods and conditions of life and travel. Instead of gathering his own experience in this regard he should be able to rely on that of others, and without waste of time devote himself to his scientific work. Every scientific investigator in the tropics knows that the information he received when he prepared for his journey of exploration into the primeval forest was practically valueless, and he had to learn for himself, often at considerable expense, loss of time and not infrequently of health.

An international, a Pan-American institution for the scientific study of the conditions of tropical America is needed. American scientists should take the lead and invite their colleagues of the Latin-American republics to join them in a systematic endeavor to study the tropics of this hemisphere, its natural riches and its diversified conditions Such a course will be as important for the preservation of peace, for the mutual understanding between the peoples of the Americas, and for the progress of these countries as commercial treaties or diplomatic conventions.

I do not propose here to enter into details in regard to the organization of a Pan-American scientific institution for the systematic study of the American tropics I do believe that the time is ripe for such an undertaking, and I have reason to think that if a suitable plan is defined and proposed it will meet with the ready response and approval of the public and the governments of all the American republics.

OCTAVE CHANUTE[1]

OCTAVE CHANUTE was born in Paris, France, February 18, 1832 He was brought to this country in childhood, was educated chiefly in New York City and began the practise of his profession as civil engineer at an early age.

After having done efficient work in railway construction in New York, Indiana and Illinois, he became in 1863 chief engineer of maintenance of way and construction of the reorganized Chicago and Alton Railroad, remaining upon that line until 1867.

During this connection, having been invited to submit a design for the proposed Union Stock Yards of Chicago, his plan was selected in competition with a number of others and he built these yards as chief engineer He was also awarded a premium for a competitive design for a bridge across the Missouri River at St. Charles, Mo. In 1867 Mr Chanute went to Kansas City, Mo., as chief engineer of the bridge across the Missouri River at that point. This was the pioneer bridge across the Missouri River, and as the river pilots and riparian dwellers had given this stream a bad reputation, the successful completion of this bridge across it in 1868 attracted great attention and interest

Later Mr Chanute successively became chief engineer of the Kansas City, Fort Scott and Gulf, the Kansas City and Santa Fe, the Atchison and Nebraska, and the Leavenworth, Lawrence and Galveston railroads

From 1873 to 1883 he was in the service of the Erie Railway as chief engineer. During this connection he readjusted the motive power of the road and lessened the grades so that the through freight trains, which averaged eighteen cars when he first became connected with the line, had grown to thirty-five cars when he closed his connection with the road in 1883, when he removed from New York to Kansas City, in order to look after his personal interests, and to open an office as consulting engineer.

In this latter capacity he took charge of the construction of the iron bridges during the building of the Chicago, Burlington & Northern Railroad between Chicago and St Paul in 1885, and of those of the extension of the Atchison, Topeka & Santa Fe Railroad, from Kansas City to Chicago, in 1887 and 1888; the latter involving, besides a number of minor streams, the Missouri River bridge at Sibley

[1] Presented to Section D, American Association for the Advancement of Science, Minneapolis, December 30, 1910.

and the Mississippi River bridge at Fort Madison.

In 1889 Mr. Chanute removed his office to Chicago, where he engaged in promoting the preservation of timber against decay, by chemical methods.

Mr. Chanute became a member of the American Society of Civil Engineers, February 19, 1868, and has contributed a goodly number of papers to its *Transactions*. In 1891 he was president of that society, in 1901 he was president of the Western Society of Civil Engineers, and was honorary member of similar societies in England, France and Chile

In October, 1891, there appeared in *The Railroad and Engineering Journal*, of New York, the first of a series of articles on "Progress in Flying Machines," written by Mr. Chanute The series was extended in the next two or three years, and in 1894 was published in book form under the above title It is a volume of over three hundred pages and it tells both of failure and progress. The author, bringing all of his resources as a skilled engineer to bear upon the unsuccessful experiments, analyzed all of the more important work done by scores of men and tried to point out, as much as might be, the causes of failure.

In the preface to the book it is stated that one of the writer's objects in preparing the papers was "to satisfy himself whether, with our present knowledge and appliances, men might reasonably hope to fly through the air." He said that in his opinion "this question can be answered in the affirmative" It meant much to the believers in the possibility of mechanical flight to have the endorsement of an engineer of the highest standing given to a discredited line of research.

In 1892 Dr. A. F Zahm, of Notre Dame (Ind) University, now of Washington, D. C., proposed the holding of an International Conference on Aerial Navigation in connection with the World's Congress Auxiliary of the World's Columbian Exposition of 1893.

In this Dr Zahm was heartily seconded by Mr. Chanute, who was made chairman of the committee, Dr Zahm being chosen secretary. The officers of the World's Congress Auxiliary, of which Mr. C C. Bonney was president, gave cordial cooperation to the plan.

The conference formed a division of the General Engineering Congress and took place in the Memorial Art Palace, in Chicago, August 1, 2, 3 and 4, 1893. It was the first aeronautical congress held in America, and the third international one

Mr. Chanute presided over the session on the opening day, the topic for the day being "Scientific Principles" In opening the conference he said

It is well to recognize from the beginning that we have met here for a conference upon an unusual subject; one in which commercial success is not yet to be discerned, and in which the general public, not knowing of the progress really accomplished, has little interest and still less confidence

The paragraph just quoted well shows the status of interest in aerial navigation in 1893. Though peculiarly conservative Mr Chanute expressed his conviction that dirigible balloons would presently attain a speed of twenty-five miles an hour, an estimate which is fully justified by subsequent events. He likewise maintained the practicability of achieving mechanical flight by gradual evolution, utilizing the results of the accumulated labors of many scientific contributors. He indicated the chief component problems already solved and awaiting solution "The equipoise," said he, "is, in my own judgment, one of the most important problems yet to be solved in aviation"

The papers read at and contributed to the conference fill a volume of more than four hundred pages. The attendance averaged about one hundred at each session, comprising the most prominent men in the engineering profession.

In the summer of 1896 Mr. Chanute began his now well-known experiments on the sand dunes with man-carrying gliders. These were continued in the following year. The accounts of this very important part of his work have been fully given in various magazines and pamphlets.

Beginning with the glider of the form which had been used by the German, Lilienthal, two

years of study and experiment enabled him to produce a type having great superiority in the matter of stability, efficiency and structural strength This was the famous Chanute biplane glider which substantially forms the conspicous body feature of the present-day biplane flying machines

For many years Mr Chanute was in regular communication, personally and by correspondence, with the leading aeronautic investigators in both hemispheres The help which he gave to such men can never be fully known, the counsel and encouragement which he gave the Wright brothers in particular have been gratefully and gracefully acknowledged by them His valuable experience, information and advice were liberally and gladly furnished to them at the time when it was most needed, when they were at the foot of the unblazed trail, and these gave them the courage and confidence which were essential to enable them to persevere and to emerge at last at the summit, triumphant

At the Boston meeting of the American Association for the Advancement of Science, held in December, 1909, Mr Chanute read a paper entitled "The Present Status of Aerial Navigation" This paper was the expression of his maturest understanding of the science to which he had devoted so many years of his life

Mr. Chanute died in Chicago on the twenty-third of November last Three daughters and one son survive him. Those who knew him will always remember his lovable character and will think of the oft-repeated saying, "He was more willing to give credit to others than to claim any for himself"

We may well believe that whenever in the future the history of aviation shall be reviewed, the name Chanute will stand forth as that of one of the few great founders

James Means

Boston, Mass

THE AFRICAN ENTOMOLOGICAL RESEARCH COMMITTEE

With a view to furthering the work of the African Entomological Research Committee, Mr Andrew Carnegie has placed at its disposal a sum of £1,000 a year for three years to defray the cost of sending a few suitably qualified young men to the United States to study the practical applications of entomology. Three of these Carnegie scholars, as they are to be called, have been selected, and two of them are already at work Dr L O Howard, chief of the Bureau of Entomology, is interesting himself in the matter and all possible facilities will be given to the scholars It may be expected that the scheme will be of value to British administration in Africa and elsewhere by providing a body of well-trained entomologists available for employment in the services of the different colonial governments

The Research Committee was appointed in June, 1909, by Lord Crewe, the then Secretary of State for the Colonies, with the object of promoting the study of the insects which play so prominent a part in the spread of disease among men, animals and plants in Africa, and Lord Cromer is its president It includes some of the most eminent authorities on entomology and tropical medicine in Great Britain

During the short period of the committee's existence satisfactory progress has been made The scheme has been energetically taken up by the African colonies and protectorates, and the large quantity of material already received at the committee's office in the Natural History Museum at South Kensington has very materially increased our knowledge of the insect pests of Africa The collections of insects, after being properly identified and recorded, are being distributed to the schools of tropical medicine, universities, museums, or other institutions where they are likely to be of value for the purpose of teaching or scientific study. Two skilled entomologists are being employed under the direction of the committee in East and West Africa respectively, for the purpose of interesting and instructing the local officials in the work, and also of carrying out special investigations.

The committee has issued quarterly a scientific journal, entitled the *Bulletin of Entomological Research*, of which the first volume is

just completed Further particulars may be obtained from the secretary of the committee, Mr. Guy Marshall, British Museum (Natural History), South Kensington, London

SCIENTIFIC NOTES AND NEWS

As a result of the recent tentative agreement between Columbia University and the Presbyterian Hospital, New York, the appointments of Dr Theodore C Janeway as attending physician and of Dr William G MacCallum as pathologist to the hospital have been announced Dr Janeway is professor of the practise of medicine in the College of Physicians and Surgeons and Dr MacCallum is professor of pathology They succeed Dr W Gilman Thompson and Dr Eugene L Opie, respectively, at the hospital

AT the last meeting of the Rumford Committee of the American Academy of Arts and Sciences the following appropriations were made To Professor D F Comstock, of the Massachusetts Institute of Technology, $100 in aid of his research on the possible effect of the motion of the source on the velocity of light To Professor G N Lewis, of the same institution, $150 in aid of his research on the free energy changes in chemical reactions To Professor R W Wood, of the Johns Hopkins University, $150 in furtherance of his researches on the optical properties of vapors

THE following fifteen candidates have been nominated by the council of the Royal Society for election to membership Professor H T Barnes, Professor A. J Brown, Professor J B Cohen, Professor W E Dixon, Professor F G Donnan, Major E H. Hills, Dr. W H Lang, Professor J B Leathes, Professor E A Minchin, Professor R. Muir, Mr. R. D. Oldham, Mr. R I Pocock, Professor A W Porter, Mr. H W Richmond and Mr. G G Stoney

M. EUGÈNE TISSERAND has been elected a member of the Paris Academy of Sciences in succession to the late Professor Tannery

THE *British Medical Journal* notes various honors conferred on Dr Paul Ehrlich, director of the Institute for Experimental Therapeutics at Frankfort. The Emperor of Russia has conferred upon him the Order of St Anne First Class, with a badge set in diamonds The King of Spain has bestowed on him the Grand Cross of the Order of Alfonso XII The German Emperor has nominated him a member of the senate of the recently founded Kaiser Wilhelm Society for the Advancement of Science, on this body he is the only representative of medicine The St Petersburg Institute of Experimental Therapeutics has elected him an honorary member The municipal authorities of Buenos Aires have given Professor Ehrlich's name to a street in the suburb of San Fernando.

A PORTRAIT of Sir William Crookes by Mr E A Walton, as we learn from *Nature*, was presented to the Royal Society before the ordinary meeting on February 16 The presentation was made on behalf of the subscribers by Professor Meldola representing about 130 fellows of the society who had contributed to the fund Sir Archibald Geikie, as president, accepted the portrait on behalf of the society Sir William Crookes expressed his thanks to the subscribers for the honor they had conferred upon him In the course of his remarks he said that in two years he hoped to celebrate the jubilee of his fellowship, as his election dated from 1863

PROFESSOR W W WATTS, F R S, has been elected president of the Geological Society of London The following awards of medals and funds have been made. Wollaston medal, Professor Waldemar C Brøgger, Murchison medal, Mr R H Tiddeman, Lyell medals, Dr F A Bather and Dr A. W Rowe; Bigsby medal, Professor O Abel; Wollaston fund, Professor O T Jones, Murchison fund, Mr. E S Cobbold, Lyell fund, Dr C G Cullis; Barlow-Jameson fund, Mr J F N Green.

WE learn from *Nature* that the Lannelongue prize, founded last year by Professor Lannelongue, of Paris, has been presented to Sir Victor Horsley, F R S The prize is a gold medal and the sum of $1,000, and it is awarded to the person who had contributed most to the progress of surgery in the ten years before the date of the award. It is open to surgeons of all nations, and is to be

awarded every five years during the annual meeting of the Société de Chirurgie.

The Fothergillian gold medal, of the Medical Society of London, given triennially, has been awarded to Dr. F. W. Mott, F.R.S., for his researches on the nervous system

President Schurman has been appointed by the faculty and trustees of Cornell University a delegate to the celebration on September 12 to 15 next, of the five hundredth anniversary of the founding of St Andrews University He has also been appointed a delegate to represent the university at the centenary celebration of the University of Christiania, Norway, to be held September 5 and 6

A six months' leave of absence, owing to illness, has been granted to Dr. E B Voorhees, professor of agriculture at Rutgers College and director of the New Jersey Experiment Station.

Professor Otto C Glaser, of the department of zoology in the University of Michigan, has been granted leave of absence for the academic year 1911–12

T D Urbahns, instructor of entomology at the Minnesota Agricultural College, has resigned to enter the government service. He will go to Salt Lake City to take up an investigation of the alfalfa weevil.

The appointment of Dr L Van Es as a member of the permanent commission of the International Veterinary Congress in the place of Dr. Leonard Pearson, deceased, has recently been announced. Dr Van Es is head of the School of Veterinary Medicine at North Dakota Agricultural College, Fargo, N D.

Captain Horace D. Bloomberg, of the U. S Army Medical Corps, who has been a member of the Army Board for the Study of Tropical Diseases, has completed his term of duty in the Philippines and is returning to the United States

Mr. K. R. Lewin, Trinity College, Cambridge, has been nominated to use the university table at Naples for six months from March 1.

In response to the request of the Chinese government for an international commission to proceed to China to investigate the outbreak of plague in Manchuria, the British government has instructed Dr. Reginald Farrar, one of the medical inspectors of the local government board, to proceed to China.

Dr C P Steinmetz, consulting engineer for the General Electric Company, was a guest of the University of Illinois during the week of March 6 to 11 During his stay he delivered lectures on "Electric Energy" and on "Transients"

Dr. E B Titchener, Sage research professor of psychology in Cornell University, addressed a convocation of the students and faculty of Indiana University, on February 23, on "Memory and Imagination" On the evening of February 9, the members of the Purdue chapter of Sigma Xi were the guests of the Indiana University chapter at a banquet and lecture. The lecture was given by Professor R. B Moore, of Butler College, on the subject of "The Rare Elements of the Atmosphere"

Colonel G W. Goethals, chief engineer of the Panama Canal, appeared as the ninth lecturer upon the J C Campbell Foundation of the Sigma Xi Society of the Ohio State University on February 21 A large audience gathered to hear him speak upon the subject "The Panama Canal" His lecture was illustrated by a large number of slides and also a film of moving pictures showing some of the machinery used upon the canal in operation.

Professor Charles H. Judd, director of the school of education at the University of Chicago, and Professor John M Coulter, head of the department of botany, spoke at the annual convention of the Central Kansas Teachers' Association, which met at Salina on March 2, 3 and 4

On February 10, Dr. Wallace W. Atwood, of the University of Chicago, spoke at Princeton, Ill, on "Conservation in Illinois," emphasizing the work of the State Park Commission, of which he is a member.

Sir Horace Plunkett, the Irish authority on cooperation in agriculture and member of

the English parliament, delivered an address before the faculty and students of the University of Wisconsin and the members of the state legislature last week on "The State, the University and the Farmer" He also held a conference with the members of the faculty of the college of agriculture on conditions of agriculture in America

THE Rational Geometry of Professor George Bruce Halsted has been translated into French and will be published by the firm Gauthier-Villars

WE regret to note the death of Professor Edwyn Carlos Reed at Concepcion, Chile He was director National Museum at Concepcion and had for many years studied the flora and fauna of Chile His work in natural history was largely devoted to the popularization of scientific knowledge and to the spread of economic ideas in economic zoology. He leaves one son, Carlos S Reed, who is now professor in the School of Viticulture

COLONEL R M BEDDOME, known especially for his publications on the ferns of India, died in London, on February 23, at the age of eighty-three years. The deaths are also announced of Dr. C Alexander MacMunn, of Wolverhampton, known for his research work in physiological chemistry, and of Dr. William Williams, of South Wales, an authority on sanitation

A BILL has been introduced into the general assembly of Illinois that provides for the establishment of a State Board of Forestry and a state forester It is provided that the office of the state forester shall be located at the State University and that the forester shall teach at the university.

A SOCIETY for the erection and maintenance of an institute for the treatment of cancer and for research, has been founded at Munich. The president is Prince Ludwig Ferdinand, doctor of medicine.

THE Vallauri prize of the Turin Academy of Sciences will for the coming three-year period be awarded for a work in Latin literature, for the following three-year period, from January 1, 1915, for the most important work published in the physical sciences. The value of the prize is $5,000.

THE Field Museum of Natural History announces its thirty-fourth free lecture course as follows

March 4—"Precious Stones, how they are Found and Manipulated," Dr George F. Kunz, New York City

March 11—"The Glacial History of the Great Lakes," Professor Frank Carney, Denison University, Granville, Ohio.

March 18—"The Sugar Maple and Maple Sugar Making," Professor L R Jones, University of Wisconsin

March 25—"Peking," Dr Berthold Laufer, associate curator of Asiatic Ethnology, Field Museum

April 1—"Picturesque Sweden," Professor James H Gore, Washington, D C

April 8—"The Real Filipino," Professor Arthur Stanley Riggs, New York City.

April 15—"Photographing the Heavens," Professor G W Ritchey, Mount Wilson Solar Observatory, Pasadena, Cal

April 22—"Recent Discoveries of Petroleum in the United States and Mexico," Dr. David T Day, U S Geological Survey, Washington, D C

April 29—"Turkestan, the Heart of Asia," Mr William E Curtis, Washington, D C.

UNIVERSITY AND EDUCATIONAL NEWS

THE sum of $7,000 has been received by the University of Michigan from the estate of Emma J Cole, of Grand Rapids, Michigan, to constitute a scholarship fund for graduate students in botany

THE regents of the University of Wisconsin have accepted as a trust the sum of $30,000 for the establishment and maintenance of a chair to be known as the Carl Schurz memorial professorship The chair is to be filled by professors from the universities of Germany The present size of the fund will make it possible to secure a German professor for one semester every second year. President Van Hise has been authorized to open negotiations with German authorities with a view to establishing a system of exchange professors between German universities and the University of Wisconsin. The es-

tablishment of the Carl Schurz professorship will be celebrated with appropriate exercises on March 31 The speakers on that occasion will include the two German exchange professors now in this country, Dr Max Friedlaender, of the University of Berlin, now at Harvard, and Professor Ernst Daenell, of the University of Kiel, Kaiser Wilhelm professor at Columbia

It was recently stated in this journal that among other conditional appropriations the General Education Board had made one for the Wesleyan College for women It should have read Western College for Women, an institution situated in Oxford, Ohio

The Kansas legislature has passed the bill to abolish boards of regents of three state schools and to substitute a commission of three to be appointed by the governor and to receive salaries of $2,500 a year each, to manage the State University, the State Normal College and the State Agricultural College

President James has asked the senate of the University of Illinois to appoint a committee to draft a university constitution, marking off the legitimate authority which should be given to such an institution by the legislature, defining the relations between the legislature and the state administration, on the one hand, and the university on the other, and dividing up and marking off the functions of trustees, faculties, students and alumni Among questions to be considered by such a committee would be the powers of university trustees, the function and power of the president, the duties of deans, the general division of the university itself into faculties, the authority of individual faculties The authority of the professor in his own department; his tenure of office; his independence of investigation and teaching, freedom of speech, pension system, salary schedule, method of determining the budget, powers of discipline of faculties over their own members and over their students are all subjects which would call for consideration in such a constitutional convention. It is proposed to submit this constitution, after it is drafted, to a full discussion, first in the senate, then in the university faculty, and finally, after working it out in detail, to submit it to the board of trustees, and after their modifications, to send it to the legislature for enactment into positive law

The University of Christiania will celebrate the centenary of its foundation in December next Dr W C Brogger, professor of mineralogy and geology, will preside as rector of the university.

Dr Alexander Smith, professor of chemistry in the University of Chicago and dean of the junior colleges, has been elected to the Mitchill professorship of chemistry at Columbia University, vacant by the appointment of Dr Charles F Chandler as professor emeritus

Dr Alfred Stengel will succeed Dr David L Edsall as professor of medicine at the University of Pennsylvania Dr John H Musser was unwilling to accept the position In the same institution Dr Milton B Hartzell has been appointed professor of dermatology in succession to Professor Louis A Duhring, who has recently been appointed professor emeritus Professor John B Deaver has been appointed professor of clinical surgery

At Columbia University the following have been advanced from instructors to assistant professors Hal T Beans, Ph D , and Floyd J Metzger, Ph D , chemistry; Everett J Hall, assaying, Samuel Osgood Miller, C E , drawing, Charles W Thomas, Mech E , mechanical engineering, Harry P Parr, Mech E , mechanical engineering, and Edward F Kern, Ph D , metallurgy

Dr. William McKim Marriott, assistant to the chair of physiological chemistry in Cornell Medical School, has been appointed instructor in biological chemistry in Washington University, St Louis.

Dr Pehr Olsson-Seffer, director of Tezonapa Botanical Station, has been appointed professor of botany at the National University of Mexico. He will lecture on the history of botany, evolution of plants and ecological plant geography, and give courses in plant physiology In the absence of botanical laboratories at the university, the work in plant physiology will be conducted at the Tezonapa Botanical Station Dr. Olsson-Seffer has also

recently accepted the post of Government Botanist in charge of the botanical section of the Biological Commission of the Department of Agriculture and of the Bureau of Forestry in Mexico

DISCUSSION AND CORRESPONDENCE

SOILS AND CROPS

If we accept Professor Chamberlin's view, "that the total eon of productive soils may be assigned a period of at least tens of millions of years" (as expressed in his article on "Soil Productivity" in SCIENCE, February 10, 1911, and if we accept his endorsement of Cameron's estimate for the United States that the capillary waters are carrying potassium toward the surface at the rate of from 40 to 83 pounds per acre per annum, while the total average removal amounts to only 23 pounds (20 pounds in crops and 3 pounds in drainage), then we might expect the potassium to accumulate in the surface soil at the rate of 1,700 to 6,000 pounds per acre per century, or at the rate of 17,000 to 60,000 pounds per thousand years, on normal level lands not subject to surface erosion, we might expect the surface soils to be many times richer in potassium than the corresponding subsoils, and the older soils to be much richer than those of more recent but similar origin

In contrast with these theoretical deductions the science of chemistry reveals the facts,[1] for example, that the common prairie lands of the oldest Illinoisan Glaciation contains as an average 12,470 pounds of potassium per million of dry surface soil and 14,050 pounds per million of the subsoil, that the more recent Early Wisconsin Glaciation contains 18,120 pounds in the surface and 19,650 pounds in the subsoil, and that the Late Wisconsin Glaciation contains 22,510 pounds in the surface and 26,690 in the subsoil.

The corresponding timbered soil types contain, in the oldest Illinoisan Glaciation, 15,100 pounds of potassium (per million of dry soil) in the surface and 16,050 pounds in the subsoil, while in the Early Wisconsin Glaciation the respective amounts are 18,080 and 21,100, and in the Late Wisconsin Glaciation there are 23,800 pounds in the surface and 26,100 in the subsoil, per million of dry soil

If two inches of water soak into a soil and if one inch escapes by evaporation and the other by subdrainage, the net result is not gain but loss of soluble minerals, under normal conditions In level or slightly undulating upland areas, such as the loess-covered prairies of the Central-West, which neither receive deposits from overflow nor lose partially depleted soil by erosion (especially while protected by prairie grasses), the operation of the natural law tends steadily toward soil depletion, with respect to the mineral elements, and this law has been in operation since the glacial or loessial age, wherever the climatic conditions have been similar to those now prevailing in our humid sections The accumulation of organic matter (including some phosphorus) in such glacial or loessial soil begins some time after its deposition and continues until a maximum is reached, after which the organic matter, as well as the valuable mineral elements, tends to decrease, the latter because of leaching, as from the beginning, and the former because the rate of decay finally exceeds the rate of growth or accumulation.

That phosphorus is an essential constituent of the living tissues of plants and that it accumulates in plant residues in prairie soils are well-established facts, but a theory that the phosphorus brought to the surface in capillary moisture exceeds that removed by crops and drainage is not supported by the composition of soils of similar origin and different age Thus ultimate analysis shows per million of dry surface soil 420 pounds of phosphorus in the oldest Illinoisan Glaciation, 595 in the more recent Early Wisconsin, and 705 pounds in the Late Wisconsin.

Even the theories of the federal Bureau of Soils and the estimates of the United States Department of Agriculture must be heavily discounted if they stand opposed to established facts; for one fact outweighs a thou-

[1] Illinois Experiment Station Bulletin 123 and unpublished data.

sand opinions based upon erroneous theories or estimates.

As a rule our meat is made from corn, and our bread from wheat. An average of the last five or six years compared with an average of a like period ten years before reveals the following data taken from the Year Books of the United States Department of Agriculture:

1. The average annual production of corn in the United States increased during this ten-year period from 2074 million to 2733 million bushels.

2. The average exportation of corn from the United States decreased from 177 million to 67 million bushels.

3. Consequently, the average annual supply of corn for our domestic use increased from 1897 million to 2666 million bushels—an increase of 40 per cent.

Now, if we keep in mind that every figure here given is based upon an average of at least five years, and also keep in mind that the population of the United States increased only 21 per cent. from 1900 to 1910, then we may well ask, if the supply of corn for home use has increased 40 per cent. and the population only 21 per cent., what have we done with such an enormous surplus of corn retained in this country?

A study of the statistics for wheat reveals the following data:

1. The average annual production of wheat increased during the ten-year period from 528 million to 669 million bushels.

2. Our average exportation of wheat decreased from 185 million to 110 million bushels.

3. Consequently, the average annual supply of wheat for our domestic use increased from 343 million to 559 million bushels—an increase of 63 per cent.

Here, too, we may well ask, if the supply of wheat for our home use has increased 63 per cent. while the population increase is only 21 per cent., what have we done with a retained surplus of wheat amounting to 42 per cent. above the increase in our population?

Under the Illinois laws about fifteen hundred township assessors report to the Illinois State Board of Agriculture the acreage of the various important farm crops grown in all the townships of the state. A comparison of two five-year periods, 1895 to 1899 and 1905 to 1909, shows that the average area of corn grown in Illinois increased in ten years from 6,950,000 to 7,340,000 acres, according to the assessors' returns, working under the same law during this entire period; whereas, according to the estimates reported by the United States Department of Agriculture, the Illinois corn area has increased from 6,910,000 to 9,700,000 acres. In other words, the state assessors report an increase of less than 6 per cent. while the federal report shows an increase of more than 40 per cent. in the average Illinois acreage of corn.

If we consider our three great grain crops, corn, oats and wheat, the Illinois state report shows the total average production to have decreased by 1 per cent. during this ten-year period, but the federal crop report credits Illinois with an increase of 41 per cent. in her production of grain during the same period.

For 1910 the Illinois State Board reports 281 million bushels of corn, while the U. S. Department reports 415 million bushels as the Illinois crop. Likewise the Ohio state officials report 105 million bushels, and the federal estimate credits the state of Ohio with 145 millions of corn produced in 1910.

All of these comparisons seem to reveal the influence of a strong spirit of optimism on the part of the federal department of agriculture, which, however, is supported neither by the assessors' report nor by the existence of any important reserve supplies, nor by the increased price of grain and meat and the high cost of plain living. In the last report of the United States Secretary of Agriculture it is stated that the value of our agricultural products rose from 4417 million dollars in 1898 to 8926 million dollars in 1910—an increase of more than 100 per cent. in twelve years; but shall we rejoice or weep when we consider that this enormous increase in value is not due to improvement of soil but to the estimated increase of acreage in crops and to

the actual increase in prices for food that must be paid by our own citizens?

On the other hand, even the crop "statistics" of the department of agriculture show that the average yield of corn per acre in the entire United States was 25.6 bushels for the twenty years 1870 to 1889, and only 24.9 bushels for the twenty years 1890 to 1909, an average decrease of 0.7 bushel, while the "statistics" for wheat show 12.2 and 13.6 bushels as averages for the corresponding periods, an increase of 1.4 bushels, with millions of acres of virgin wheat lands brought under cultivation. As an average the "statistics" show an increase of 7 per cent. in yield per acre for these two greatest food-grain crops; while our population actually increased 51 per cent during the same period. Curves projected from these data may not be alarming to those of the present generation who have not yet felt the high cost of living, but they look less comfortable for our own children.

True optimism is admirable, but blind optimism is dangerous. The undersigned has great faith that permanent general prosperity and progress will ultimately be secured for the people of the United States—not that kind of existence enjoyed (?) by the densely populated sections of China, which requires frequent readjustments, as now in progress[3] with the certainty of a sudden reduction in population numbered by the million; not a condition under which men and even women gather "the katamorphic products of human food-consumption" for a year, in order to recover and return to the soil an amount of phosphorus per individual equal in value to that for which we now receive at our phosphate mines only two cents from the exporter, but we seek rather a higher civilization whose achievement shall be based upon a knowledge of the fact that to insure permanent prosperity we must increase production and limit reproduction—especially the reproduction of the unfit, whose support in penal and charitable institutions already consumes about half the total revenues of the state governments.

Even though the high civilization of the ancient Mediterranean countries "went down into the dark ages with laughter," all must recognize and admire the recent agricultural developments in western European countries; but shall we ignore the fact that for five million dollars we are exporting annually to Europe a quantity of our highest-grade phosphate sufficient for the production of 1400 million bushels of wheat, that would be worth at least a thousand million dollars to the oncoming generations of Americans?

It is true that Denmark produces 40 bushels of wheat per acre, compared with 14 bushels in the United States, but Denmark produces only 4 million bushels of wheat, and then imports 5 million bushels of wheat, 15 million bushels of corn, the same amount of barley, 800 million pounds of oil cake, as much mill foods, and large amounts of phosphates, saving and using the imported fertility; and paying for it all with profit by exporting hundreds of millions of pounds of butter and bacon to a country whose degree of prosperity is measured by her profits from trading upon the prosperity and poverty of other larger countries.

The fundamental doctrine of the United States bureau of soils is indeed a pleasant one, and highly important if true, but exceedingly dangerous and condemnable if not true. It reads as follows, in exact quotations:

1. "That practically all soils contain sufficient plant food for good crop yields; that this supply will be indefinitely maintained."—Bureau of Soils Bulletin (1903) 22, p. 64.

[3] Nanking, China, February 3, 1911.—That the deaths due to famine and the pestilence following in its wake will total a million before spring was the estimate submitted to the relief committee here to-day. Relief workers are aghast with the realization of the task before them. Even were they in receipt of unlimited contributions for relief, the missionaries, doctors and other volunteer workers would be almost hopeless in the face of two and one half millions of suffering people in the Anhui and Kiang Su provinces. The famine is an old story in China, but the most experienced relief workers declared to-day that the present prospect is the worst in many years.—*From Press Dispatch.*

2. "There is another way in which the fertility of the soil can be maintained, viz, by arranging a system of rotation and growing each year a crop that is not injured by the excreta of the preceding crop"—U S Farmers' Bulletin (1906) 257, p 21

3 "The soil is the one indestructible, immutable asset that the nation possesses It is the one resource that can not be exhausted, that can not be used up."—Bureau of Soils Bulletin (1909) 55, p 66

4 "From the modern conception of the nature and purpose of the soil it is evident that it can not wear out, that so far as the mineral food is concerned it will continue automatically to supply adequate quantities of the mineral plant foods for crops"—Bureau of Soils Bulletin (1909) 55, p 79

If again we turn from theory to science, we find at the Rothamsted Station in a four-year rotation, including always a legume crop, that the yield of turnips decreased from 10 tons in 1848 to less than 1 ton per acre as an average for the last 20 years, that the barley decreased from 46 bushels in 1849 to 14 bushels as an average for the last 20 years; that the clover has decreased from 2 8 tons per acre in 1850 to less than one half-ton average since 1890, and that the wheat produced 30 bushels in 1851, and 33 bushels average during the next 12 years, but only 24 bushels since 1890, and 20 bushels per acre since 1900

As an average of the last twenty years the value of the four crops on the unfertilized land at Rothamsted is $33 83 (from four acres), but where the same crops were grown on adjoining land to which mineral plant food had been applied the average value is $76 83, the increase being 140 per cent above the cost of the minerals Let us thank God for Rothamsted, and be grateful that agriculture has some facts.

Likewise at State College, a four-year rotation, including clover, has been practised for nearly thirty years, but as an average of two consecutive 12-year periods the value of the four crops (corn, oats, wheat and hay) decreased from $44 20 to $32 72, but where mineral plant food was applied the crop yields averaged 49 per cent above the unfertilized yields

Both the teaching of science as applied to agriculture and the practise of farming, in America, have suffered and still suffer from an insufficient accumulation of facts and from an over-production of theories and conclusions

While famine is frequent in China and Russia and almost constant in India—the only great populous agricultural countries comparable with the United States in necessary self-dependence—and while the beautiful level upland Leonardtown loam soils of southern Maryland, near the city of Washington, still lie agriculturally abandoned, with only 80 pounds of total phosphorus and 500 pounds of total calcium per million in the surface soil (facts discoverable even in Bureau of Soils Bulletin 54), shall we encourage the Whitney-Cameron doctrine[6] *that it is never necessary at any time to introduce fertilizing material into any soil for the purpose of increasing the amount of plant food in that soil?*

CYRIL G HOPKINS

UNIVERSITY OF ILLINOIS

BROWNIAN MOVEMENTS AND MOLECULAR REALITY

TO THE EDITOR OF SCIENCE I have recently received a copy of Mr F Soddy's English translation of Professor Jean Perrin's paper on "Brownian Movements and Molecular Reality" Its perusal recalls to mind some ideas I have entertained for a number of years relative to a general physical theory based on very simple facts or principles The earliest record I have of these ideas is in a memorandum note of November 10, 1897. In a letter of January 30, 1900, to Professor Peter S Michie, of the department of philosophy, U S Military Academy, West Point, the ideas referred to were outlined rather more clearly and I also presented a brief statement of them under date of August 11, 1900, to the International Congress of Physics which was held at Paris in connection with the Universal

[6] Hearings before the Committee on Agriculture of the United States House of Representatives (1908), page 446; or Ginn & Company's "Soil Fertility and Permanent Agriculture," page 315.

Exposition of that year. A brief paper on the subject was presented to the American Physical Society in 1903, and an abstract of this paper was published in the *Physical Review* for April, 1903, but the complete paper with diagrams has not been published. The title of the paper was "A Simple Geometrical Principle and its Possible Significance in Connection with a General Physical Theory," and the principle referred to was stated as follows:

In an aggregation of an indefinite number of equal spherical bodies an arrangement giving minimum total volume and perfect symmetry throughout is impossible.

Three different arrangements of a group of spherical balls of equal size were considered: arrangement A, in which twelve of the balls are grouped about a central one, so the surrounding balls are tangent to the central one and to each other throughout; arrangement B, in which twelve balls are symmetrically disposed about and touch a central one, but nowhere touch each other, and arrangement C, in which the balls have the cubical arrangement, or the one in which the mutually tangent planes form cubes. The following is quoted from the published abstract referred to above:

The assumption is now made that the balls come together in a collection under their mutual attractions according to gravity laws. They will not assume or remain in arrangement C because while this gives symmetry throughout it is not the most compact possible and the equilibrium of the collection would be unstable.

Arrangement A, while the most compact possible for an indefinite number of balls in contact throughout, is not entirely symmetrical.

Arrangement B gives a perfectly symmetrical disposition of twelve balls with respect to a central ball but it is geometrically impossible throughout a collection of a greater number than thirteen.

It is suggested that under the conditions assumed the result will be that the balls will assume no fixed arrangement, but that they will be in continual relative movement, striving after the unattainable arrangement that will give minimum total volume, symmetrical disposition, and therefore fixed stable equilibrium throughout.

So far as I can now recall, I had not learned of the Brownian movements at that time. I certainly did not have this phenomenon in mind when the paper was written. I have not been able to make out that Professor Perrin's paper contains any very clear explanation of or theory as to the underlying *cause* of the Brownian movements, or that it purports to suggest such an explanation or theory, but the relations between the actual phenomenon as described and the above quoted speculation seemed to me rather striking.

In my mind the Brownian movement paper tends to confirm the idea that the "simple geometrical principle" above described is deeply significant, if it is not indeed a general and fundamental principle of physical phenomena.

JOHN MILLIS,
Col., Corps of Engineers, U. S. Army

FURTHER EARLY NOTES ON THE TRANSMISSION BY FLIES OF THE DISEASE CALLED YAWS

I HAVE previously published in SCIENCE[1] two notes on the transmission of this tropical disease by flies. The earlier reference bears date of 1769 from Guiana. The second, while of much later date (1817), indicates that in Brazil at that time the infection was conveyed by a certain fly recognizable by its small size.

Shortly after the publication of this second note, I received a letter from Professor J. B. Woodworth, leader of the Shaler Memorial Expedition to Brazil in 1908–09, in which he kindly called my attention to a further account of this phenomenon in Walsh's "Notices of Brazil." While spending the recent holidays at Washington at work in the Library of Congress, I looked up this reference and also found another and earlier statement. Believing that these accounts may not be devoid of interest and value, they are herewith reproduced.

The one referred to by Professor Woodworth is found in "Notices of Brazil in 1828 and 1829," by R. Walsh, published in Boston in 1831. On page 224 of volume I. we read:

A disease, called in the country *bobas*, is frequently attended with fearful consequences. It

[1] January 7 and November 4, 1910.

resembles the frambesia or yaws of the West Indies. The body swells and breaks out into ulcers, which have often the appearance of mulberries, and the patients become exceedingly loathsome. It is infectious by contact, but is also communicated, *according to the theory of the country*,[6] in a manner that defies all precaution. The eye sometimes is partially affected, and a small fly is then attracted by the discharge; this insect comes loaded with the contagious matter, and communicates it to the next person, on whose face he happens to light.

It will be noted that Walsh agrees with Koster's statement[7] that the disease is transmitted by a certain "small fly from which every precaution is oftentimes of no avail" and that the eye is the part most likely to be affected.

An earlier account of this means of infection is found in J. G. Stedman's "Narrative of a Five Years' Expedition Against the Revolted Negroes of Surinam, in Guiana on the Wild Coast of South America," London, 1796. On page 274 of volume II. he writes:

The yaws, a most disagreeable disorder, by many compared to the venereal disease, renders the patient a shocking spectacle, all covered over with yellow ulcers. To this last mentioned loathsome malady most negroes are subject, yet but once only in their lives, in which, and in being very infectious, it resembles the small-pox. Indeed, if a fly which has been feeding upon the diseased (and they are generally covered with them) lights upon the slightest scratch on a healthy person, it communicates this dreadful disorder, which always confines him for several months.

The earliest references to this disease which I have chanced upon are from William Piso. The first occurs under the heading De Lue Venerea on page 35 of his De Medicina Brasiliensi in "Historia Naturalis Brasiliæ," by William Piso and George Marcgrave. Under the heading De Lue Indica the same facts are given almost verbatim on page 43 of Book II., De Natura & Cura Morborum, Occidentali Indiæ, imprimis Brasiliæ, familiarum, in Piso's "Historiæ Naturalis & Medicæ Indiæ Occidentalis," one of the component parts of "De Indiæ Utriusque Re Naturali et Medica," by William Piso and Jacob Bont. The first was published at Leyden and Amsterdam in 1648, the second at Amsterdam by the Elsevirs in 1658.

That part of the account of the disease which is of interest to the general reader translates as follows:

Concerning the Venereal (or Indian) Disease (or Plague). This is a disease which occurs not only in children as a result of inheritance from their parents, and is contracted not only by infection in sexual union, but even by lighter contact. It originates chiefly in fetid and decaying food, and in rancid and corrupt drink. It rages not only among Negroes and Indians, but also among Portuguese and Dutch. The whole body is infested with schirrhous tumors and virulent ulcers. This disease is indeed endemic in that region [Piso was writing of northern Brazil] and by both Spaniards and Brazilians is called *Bubas*.

Careful search failed to show any reference to insects as agents of transmission.

A THEORY OF SEX DETERMINATION[1]

Mrs. Laura A. Calhoun, a woman of culture, who has had considerable experience in the breeding of animals in California, ventures on the strength of this experience and that of others to propose and develop a theory of the conditions determining sex.

Her main thesis is set forth in these words: "The sex of the embryo in man and the higher animals is determined in the ovary from which the ovum in question is developed. In the normal female, the ovary of the right side yields ova which on fertilization develop as males, and the ovary of the left side yields ova which are potentially female."

From this arises the practical deduction that sex can be determined at will, through the service of gravitation. For the prospective mother to lie on the right side should

[6] Italics by the present writer.

[7] See "Note," etc., November 4, 1910.

[1] "The Law of Sex-determination, and its Practical Application," by Laura A. Calhoun, The Eugenics Publishing Company, New York.

ensure male offspring. To allow the spermatic fluid *to flow to the left side means female* offspring.

Besides the main thesis, Mrs. Calhoun takes up the general subject of heredity, with quotations from leading authorities, matters likely to be interesting and helpful to those for whom the book is written, much of this being addressed especially to women. A new theory, called telegyny, is suggested, the effect of the first female on the male, a theory which is probably as well founded as its prototype, telegony, the supposed effect of the first male on the female, a scantily supported hypothesis, thus far lacking adequate verification.

Mrs. Calhoun writes in a frank, modest, friendly style, which disarms technical criticism The present writer is not convinced that the theory in question is correct. But to say this is only to say that one of the central problems in biology still awaits a final decision

QUOTATIONS

THE ANTIVIVISECTIONISTS

BECAUSE a woman, crazy about cats, subsidized a lawyer and a press-agent for an indefinite length of time, the state of New York must face every year some bill aimed at scientific research There are various organizations of this type, varying in the amount of absurdity and of harm The Society for the Prevention of Cruelty to Animals has possibly put an end to its usefulness by swinging over to the antiexperiment camp The act which has been introduced this year shows that the American societies, defeated again and again, have taken a lesson from England and are now asking for investigation instead of restriction Pasteur and Koch could not have done their work as the British law stands to-day. Of course, investigation is a plausible term. As a matter of fact, what the opponents of scientific progress object to is experiments which are fully set forth in scientific publications. Investigation would be a mere form of sentimental agitation. The scientists make no concealment of what they are doing On the contrary, they give it all the publicity they can obtain. We can hardly believe that the present is a favorable moment for these dangerous sentimentalists to succeed The death-rate from meningitis only two or three years ago was from seventy to eighty per cent. Now the rate, counting all cases, is twenty-five per cent, and in the cases where the serum is given early it runs as low as six to eight per cent Among those cases which were called cured before the serum was discovered were the long-drawn-out and most painful ones which left imbecility or some frightful deformity. These cases now have absolutely disappeared As this triumph over one of the most terrible and agonizing diseases, from which the principal sufferers are children, is so fresh in the mind of the public, it hardly seems possible that a backward step should be taken Dr Flexner and the Rockefeller Institute, in conquering meningitis, used twenty-five monkeys and about two hundred guinea-pigs and rabbits

There is one dreadful and destructive disease which men hesitate to name. It struck down not only the guilty, but millions of innocent women and millions of innocent children That disease has within a few months been mastered by a drug, the most perfect drug antidote in the world. The cost of conquering this disease was a few rabbits and a few mice.

Dr Carrel, only a short time ago, perfected the delicate operation of transfusion of blood, which is now saving many lives. The cost here was a few kittens, the societies would much rather have had the kittens put into a bag and thrown into the river

Infantile paralysis filled this country with terror a few months ago. The experiments which have taken place since then mean that this disease will be handled much better next summer, and there is every promise that before long it will be exterminated. Doubtless in the process a few animals will meet their death in the service of science, instead of in the ordinary form. There are a number of mice now suffering from cancer in order that

one of the most deadly and most painful of diseases may be conquered. The Society for the Prevention of Cruelty to Animals ought to bend all of its energies to stopping the men of science from making any use of these mice If they do not successfully interfere, it is likely that cancer may be conquered as thoroughly as diphtheria, which has been reduced from one of the most destructive scourges of children to a point where, if the antitoxin is taken in the first twenty-four hours, the death-rate is only about one and a half per cent

A fight is going on against the gipsy moth, the hookworm, and other well-meaning inhabitants of the globe We suggest that bills be introduced by humanitarians into all the legislatures to protect these guiltless creatures Rats are unpopular just now because of the fact that they carry the bubonic plague and other diseases. There ought to be organized at once a society for the protection of rodents

The more reasonable these bills may be made to sound, the more chance there is that they may accomplish some unspeakably fatal blow against the human race. There are laws now in plenty forbidding cruelty. The great institutions which are specially aimed at by the cranks, like the Rockefeller Institute, are in the hands of men who are spending their lives in the cause of solid and real kindness Shall we take away from splendidly equipped experts of devoted character the right to judge what experiments are necessary, and put the question into the hands of some fool committee made up of persons in whom hysterical excitement takes the place of knowledge?—*Collier's*

SCIENTIFIC BOOKS

ELEMENTARY BIOLOGIES

BIOLOGY is unique among her sister sciences in the wealth of variation in the methods of presenting the subject to beginners It has been truly said that there are as many methods in this work as there are men conducting it. In the minds of many, this is as it should be, for there are requirements for one which are not for another The technical school emphasizes certain things which will not form a part of the course given in the classical college The material or *content* varies

It is a question in the writer's mind as to how much the *method* of presentation should vary in the several conditions The following well-marked methods of teaching beginning biology are recognizable (1) Biology as an integer, not resolved into its components, zoology and botany As subdivisions of this category, one finds (*a*) The type method, introduced into this country when Martin, in 1868, adapted Huxley's "Biology" to the students entering American colleges at that time The evolutionary chain was emphasized and morphology was predominant (*b*) The two-type method, which Sedgwick and Wilson used in their text, one animal and one plant being selected and studied exhaustively, others being presented as comparisons The functions of living matter were considered equally with the morphological features (*c*) A method, not especially new but well marked in the "General Biology" of Needham,[1] where the *principles* are emphasized, illustrations being selected towards that end and morphology reduced to a minimum, types as such are scarcely recognizable With the second great division (2), the science is resolved into its components, zoology and botany, but we may distinguish here, as before, well-marked subdivisions, (*a*) where the biological aspect is maintained and (*b*) where the work is presented as purely botany and purely zoology, with no reference to the common ground between them.

There have been published recently, in this country and abroad, several books whose purpose is to fill one of the fields given above Kirkaldy and Drummond[2] have followed 1*a* in giving a discussion of isolated types, with little intercommunicating cement. If biology is a science, as chemistry is a science and physics is a science, having definite content and definite principles, one would never de-

[1] Comstock Publishing Co, Ithaca, 1910

[2] "An Introduction to the Study of Biology," Oxford, 1909.

termine the *fact* from this English text There is left in the mind of the student a series of chapters from the story-book of living things, each complete in itself and bearing only remotely upon what precedes or follows The clever student will find the thread, but only he.

At the present time, no text has been written from the point of view of the Sedgwick-Wilson method, although there is in progress a book which will embody this idea, the types being somewhat different Therefore it can not be assumed that this method is being abandoned, as judged by the production of texts representative of it

The text of Professor Needham, referred to above, must be classed separately As we have already said, principles are considered in the light of selected examples, which are described in so far as the matter in hand demands If this point be borne in mind by the reader of the book, he will scarcely urge the criticism that the treatment is superficial The illustrations, many of which are original, are supplemented by photographs, and the quality of book-making is such that the figures, although inelaborate, are ample The absence of time-honored pictures is refreshing The attempt to bring into the book the results obtained in the laboratory of the investigator of the present is happily accomplished The work of the American school of cytologists and the experimental or analytical school in general is covered, briefly, it is admitted, but, in the mind of the reviewer, logically and sufficiently clearly to be appreciated by the student Much of the data of the volume concerns the insect world and this is readily understood when the principal interest of the author is considered It may be said that there is little material discussed in the book which is not readily placed in the hands of the students of any institution

The beautifully illustrated little book of Dr. Kraepelin[3] is moulded in a manner similar to the text of Needham. Professor Needham's book may be used as a laboratory guide and field companion, and in this respect it differs from all other texts mentioned here, with the possible exception of the one of Hegner It is a matter much to be regretted that the students of American institutions of learning, even after they have passed two or three years in the work, are unable to use books written in foreign languages There is no English volume which can approach this German book in wealth of text-figures, some of which are colored The text itself is well in keeping with the book-making, and in the experience of the writer the book as a whole is inspiring to the student who can master the written word, little as it may be The futility of presenting a book of the quality of Kraepelin's to English students is readily seen when one attempts to translate the book into English and put it upon the market at a German standard, still maintaining the selling price of the original (four Marks) Some cooperation may sometime be possible between the departments of Romance and Germanic languages and the scientific departments of our universities and colleges which may be beneficial to both.

McFarland's[4] book can scarcely be called a text, but rather a reader As such it will be useful, although the illustrations are poor throughout, many of no value whatsoever and the language is at least the limit of possibilities for the average student of beginning biology He will be found clamoring for Anglo-Saxon words when he opens the first chapter to read

> To study the problems of life apart from their cosmic relations is to lose much of their significance It is only by an appreciation of the endless changes—integrations and disintegrations—that pervade the universe that one comes to realise that those qualities by which we recognize living substance more or less closely correspond to the qualities of all substance and those forces by which it is animated to those forces by which the universe itself is controlled.

The medical side of the book is evident in the later chapters of the volume, such as

[3] "Einführung in die Biologie," Teubner, Leipzig, 1909. (Stechert)

[4] "Biology, General and Medical," Saunders, Philadelphia, 1910.

Blood Relations, Parasitism, Grafting, Senescence and Mutilation and Regeneration. When it is considered that more than nine tenths of the students taking the course in beginning biology go no farther in that department, we come to realize that our course should be so shaped that this great majority receive the consideration, and not the few who later become students in higher courses. It is for this reason, if for no other, that the economic side of the subject is warranted. Not that this be overdone. There is a danger that our references become so anthropocentric that we shall need another Galileo; man must be kept in his proper relation with the universe at large, and bacteria, moulds, pathogenic protozoa and antibodies must be seen to be part and parcel of this universe and not designed as helpers or scourges of mankind.

There is in this book a laxity in attention to details that will be discovered by the careful reader. Regeneration and continuous growth are two different things, although the author treats them as one. Mitosis precedes the appearance of the bud in the growing yeast and not *vice versa*. The granular theory of protoplasmic structure is *not* generally conceded. The figure of a typical cell, copied from Huber, is wretched and misleading. But it is easy to tear down and hard to construct. The book is inspiring to the student who looks broadly at the subject and one wishes it were more adapted to the needs of the modern American boy.

Hegner[8] has designed his text to occupy the first half year of a course where the second half year is devoted to vertebrate zoology. But it is not, *sensu strictu*, an invertebrate zoology. It falls in our category, 2*a*, being a biology with especial reference to invertebrates. The attempt is made to present the newer zoology to the beginner. Here we find the figures of Jennings, Yerkes, Morgan—in fact it may be called an American product from cover to cover. Consequently, the student finds himself at home at once among American forms and American names. It is not to be understood, however, that the view is circumscribed and that the data from foreign sources are eliminated.

[8] "An Introduction to the Study of Zoology," Macmillan, 1910.

Leaving aside for the present time the value of introducing the student directly to the unseen world of the protozoa, it may be said that the result is excellent in the light of the labor set before its author. The book-making is good, the illustrations are carefully selected and there is a unity in the volume which appeals very strongly to the reviewer. There are, as before, places where changes in future editions may be suggested. It is discouraging to the student to be introduced to pages of Greek and Latin terms at the outset. Sufficient unto the later pages is the evil thereof; let us not blunt his zeal at the start. The description of photosynthesis is so involved with that of respiration that the average student will not untangle them, and when the statement is made that "one group of processes (respiration) uses the waste products of the other (photosynthesis)" the error is obvious, for while this may be so for a part of the time, the relation does not exist at others (in darkness). As Professor Alexander Petrunkevitch has pointed out, the figure from Dahlgren and Kepner illustrating the alveolar hypothesis of protoplasmic structure is wrong, inasmuch as this theory involves a foam structure and not that of an emulsion. Amitosis should not be given the prominence that it enjoys in the book, whatever the personal views of the author, for the statements are not warranted by recent investigations. Moreover, the selection of Wheeler's drawings of amitosis in the follicles of the insect ovary to illustrate amitosis as a process of cell-*multiplication* is not fortunate, inasmuch as there is only *nuclear* and not cytoplasmic division. Maupas's schema of the effects of isolation from conjugation in *Paramecium* is given, although the text states, rightfully, that the work of Woodruff and others, such as Gregory and Jennings, has led to a different interpretation. Schultze's figures of the development of the sponge are adopted, although there is perhaps nowhere in biology a more difficult bit of

ontogeny to understand and to leave these figures without complete description is to give the student the impression that simple epiboly is involved These are but passing thoughts and are not in any way meant to detract from the value of the book

The question, however, remains, how many institutions could equip their students with the apparatus which is practically necessary for the carrying on of work along the lines laid down by Hegner? It will be remembered that the exact studies on the behavior of protozoa were made possible through the application of the Greenough binocular microscope in the hands of Jennings and others The time necessary for the development of technique for such experimental work had better be spent, in the mind of the present writer, in covering the subject of biology somewhat more broadly Again, there are not many students in the first year in the subject who could make much of a series of demonstrations of the development of *Cambarus* It may be that the present writer does not understand fully the *raison d'être* of the book and that the illustrations are not covered in the laboratory If this is true, why bring into the student's mind at all the intricacies of crustacean development? It does not involve any more completeness, for there are still many things left out of consideration, such as phylogeny Does embryology rightly form a part of the beginner's training? Above all, dogmatism is the *bête noire* of all teaching Is it not necessary to be dogmatic in teaching embryology in this course? Can the data be verified by the student?

It is the firm belief of the present writer that the division of the subject into its two grand divisions is a decided loss to the general student. Living things, after all, partake of the same general characters The more plants are studied in terms of animals, the better they have been understood The best zoologist is he who has had at the same time the best botanical training. If it be urged that there are few men who are capable of covering the two fields well, the answer may be made that it is so much the more deplorable. Specialization is carried too far even for the good of investigation if the zoologist can not think in terms of plants The great principles of the science have been formulated by studies upon both plants and animals A well-marked instance of this is the present-day work in genetics, in sex, in growth and the like If this is true, why not give the student the advantage of it?

It is the belief of the writer, too, that more than one year can very seldom be given by the general student to any one science Unless he be a prospective student of medicine, sanitation or biology itself, his major work must of necessity take him into other fields The deplorable ignorance of the average art student in things biological would be more quickly effaced if he were able to gain in one year a comprehensive course in this subject comparable to that he may receive in physics and in chemistry. To present the subject as zoology and botany defeats the end

The physicists and chemists have found time from their research to discuss teaching methods in their respective subjects, but the biologist—well, the biologist is made of finer stuff A symposium upon elementary biology at the American Association, resembling the discussions of the chemists and physicists which have been held in the past, would be most valuable to all who are concerned, directly or indirectly, in presenting the subject to the students of our universities and colleges

MAX W MORSE

TRINITY COLLEGE

Metabolism in Diabetes Mellitus By FRANCIS G BENEDICT and ELLIOT P JOSLIN Carnegie Institute of Washington 1910

The book contains 193 tables It has the detailed record of work on thirteen cases of diabetes, ten classed as severe and three as light Calorimetric measurements have been made, the carbon dioxide excretion and oxygen absorption recorded, urinary analyses accomplished, and the influence of food observed It represents the most ambitious attempt yet made in the study of human diabetes and is a

sincere endeavor to elucidate the problems connected with this disease

One of the most interesting features of this very extensive and laborious piece of work is the discovery of a constantly low respiratory quotient in patients suffering from severe diabetes, which accords with theoretical expectations

On page 211, the authors state that after giving beefsteak to a diabetic, "the excretion of sugar in the urine was not sufficient to indicate the excretion of a large part of the non-nitrogenous portions of the steak in the urine" But the sugar rose from 3 1 grams per hour to 8 6, an increase of 5 5 at the same time that the nitrogen elimination rose from 0 57 to 1 25, an increase of 0 68 grams per hour, which corresponds to increased protein destruction of 4 3 grams! According to this computation, 5 5 grams of dextrose might have arisen from 4 3 grams of protein which certainly does not support the negation quoted above

The reviewer is forced to disagree with the main contention of the book, that the heat production in severe diabetes is 15 per cent higher than the normal The error of Benedict and Joslin is twofold In the first place, their group of normal individuals, nine in number, include three weighing respectively 74, 80 and 83 kilograms These are not fairly comparable with diabetics weighing between 45 and 65 kilograms In the second place, the high metabolism obtained from a diabetic individual weighing 45 kilograms who was "extremely highstrung, nervous and apprehensive," and "not an ideal subject," plays quite a part in the average results upon the diabetic patients If the heavier, normal individuals be excluded, then six weighing between 48 and 67 kilograms produce 1 27 calories per kilogram per hour, and if the excitable diabetic be excluded, it is found that five individuals with severe diabetes and weighing between 49 and 65 kilograms, show an average heat production of 1 34 calories per kilogram, which is an increase of 5 per cent. above the normal, or about that obtained by other observers

NOTE ON A CONGLOMERATE DIKE IN ARIZONA

While mapping the surface geology of Silverbell, Pima County, Ariz, in connection with a study of the ore deposits of that district, the writer found a conglomerate dike which seems to differ enough from the majority of clastic dikes previously described to justify a short note on its occurrence and probable origin

On a claim known as C M C No 4, about a mile north of the town, one of the many intermittent streams of the region has cut a gulch in a dark-colored quartz-porphyry In the bottom of this gulch and running parallel to it is a vertical fissure from six to eight inches in width filled with a hard compact mass of fragmental material. The fragments are generally angular and vary in size from grains of exceeding fineness to pieces of rock two inches or more in diameter. The greater part of the material is the quartz-porphyry that forms the walls, but a variety of other igneous rocks known to occur in the hills beyond the head of the gulch is also notice-

able. The depth of the fissure is unknown, but the drop in the stream bed showed a downward extent of six feet in which there was no perceptible decrease in width. The dike is parallel to the jointing in the porphyry and can be traced for over fifty feet before it pinches out. It is marked by a number of pinches and swells, giving the formation the appearance of several long, thin, connected lenses of conglomerate standing vertically in the porphyry.

The obvious explanation is that a fissure in the igneous rock has been filled by stream wash, afterwards cemented by calcareous waters, but the origin of the fissure is by no means as clear. Many of the clastic dikes hitherto described have been attributed to the squeezing up from below of fragmental material, while in those filled from above there usually has been evidence of considerable local disturbances to account for the formation of the open fissure.[1] For reasons that can not be given here, but which will be given in a forthcoming paper on the district, it is fairly well established that there has been at Silverbell no recent rock movement sufficient to form open cracks in any of the rocks. It seems more probable that the dike in question represents the result of a joint plane enlarged by weathering, and filled in part by the products of this weathering and in part by sediment washed in by the stream. It is therefore a local feature, and bears no relation to the dynamics of the district, although superficially resembling clastic dykes that have been the result of distinct orogenic movements.

NOTE REGARDING MAIZE FLOWERS

It may be well to make here the preliminary announcement of some results obtained in the continuation of my studies of the evolution of the "ear" of Indian corn (maize) begun some years ago. It will be recalled that I published in the *Popular Science Monthly* for January, 1906, a paper entitled "What is an Ear of Corn?" in which I homologized the "ear" with the central spike of the ordinary "tassel," of staminate spikelets. Continuing my studies I have now found perfect flowered (hermaphrodite) spikelets in well-developed "ears" occupying the usual lateral position upon the plants. These are fully figured in a paper which is nearly ready for publication under the title of "Perfect Flowers in Maize." It is found that these are produced upon plants that differ markedly from the ordinary type of Indian corn (maize). They are short-jointed, with broad, leathery leaves, and I venture the suggestion that those plants may resemble in some degree the original form from which our common maize was derived. One of the photographs shows the remnants of an abortive second flower in the pistillate spikelet near the well-developed kernel taken from one of these perfect-flowered ears, indicating that these spikelets were once two-flowered.

THE INDIANA ACADEMY OF SCIENCE

THE twenty sixth annual meeting of the Indiana Academy of Science was held in Indianapolis, Friday, November 25, 1910. The president of the academy, Professor P. N. Evans, chose as his subject for his annual address, "The Place of Research in the Undergraduate Schools." Forty-two regular papers were presented. Those of most general interest were as follows:

"Plants and Man—Weeds and Disease," Robert Hessler, of Logansport.

"Indiana Municipal Water Supplies," Charles Brossman, Indianapolis.

"Subterranean Drainage in the Bloomington Quadrangle," J. W. Beede, of Bloomington.

"Conservation Problems," Frederick J. Breeze, of Lafayette.

"The Properties and Reactions of Thrombin," L. J. Rettger, of Terre Haute.

"The Nature and Origin of the Fish Fauna of the Plateau of British Guiana," C. H. Eigenmann, of Bloomington.

"A Physiographic Survey of the Terre Haute Area," Charles R. Dryer, of Terre Haute.

"Paleolithic, Neolithic, Copper and Iron Ages

in Shelby County," F. W. Gottlieb, of Morristown.

"The Temperature Coefficient of the Surface Tension of Water," Arthur L. Foley, of Bloomington.

"Gaseous Fermentation in Sweetened Condensed Milk," O. F. Hunziker, of West Lafayette.

"Weed Problem in Indiana," Stanley Coulter, of Lafayette.

"The Water Balance of Desert Plants," D. T. MacDougal, of Tucson, Arizona.

"Indiana Fungi," J. M. Van Hook, of Bloomington.

"An Ecological Survey of the Lower Whitewater Gorge," M. S. Markle, of Richmond, and L. C. Petry.

"Timothy Rusts," A. G. Johnson, of Lafayette.

In the evening Dr. D. T. MacDougal, of the Desert Laboratory, at Tucson, Arizona, gave a very interesting and instructive illustrated lecture on "Desert Days and Desert Ways."

Professor Charles R. Dryer, of Terre Haute, was elected president of the academy and A. J. Bigney, of Moores Hill, secretary.

A. J. Bigney,
Secretary

SOCIETIES AND ACADEMIES

THE WASHINGTON ACADEMY OF SCIENCES

The 67th meeting of the Washington Academy of Sciences was held, under the direction of the president, Dr. F. W. Clarke, at the Cosmos Club on the evening of January 19, 1911.

Dr. F. M. Jaeger, professor of inorganic and physical chemistry in the University of Groningen, Holland, gave an address on "Anisotropic Liquids and so called Fluid Crystals."

Numerous experimental researches have established the fact that in certain liquids, and under certain conditions, there are forces that act upon the molecules differently in different directions. Hence the conception of the liquid state as one characterized by irregular molecular motion is no longer tenable—a fact that fills the subject with interest and has led to many an ardent discussion.

Dr. Jaeger pointed out the similarity of solid crystals with easy gliding planes, to liquid ones, and the analogy of their changes to those of polymorphic substances. He also described their phase transitions and in particular showed the properties of substances that melt successively to three or more stable liquid states.

By means of projections he showed such properties of liquid crystals as their form, dichroism and strong birefringence, and made clear his argument that the emulsion theories advanced by some to explain the observed phenomena, are only based upon the misunderstood turbidity due to birefringent liquid phases. He also illustrated the strange phenomena of "enforced" and "spontaneous" pseudo-isotropy, and showed the axial images of clear, uniaxial liquids and their strong rotating power.

Proceeding to the real anisotropic liquids, which he illustrated by the different properties of p-azoxypenetol, he discussed the principal differences between the spheres of such liquids and real crystals, their heat motion and their diffraction phenomena when mixed with other substances, and concluded with an elucidation of their magnetic induction.

The formal presentation of the paper and its discussion were followed, after adjournment, by experimental demonstrations to many of the more interested of the audience.

The 68th meeting of the Washington Academy of Sciences was held at the Cosmos Club on the evening of February 1, 1911, with President F. W. Clarke in the chair.

Dr. W. D. Bancroft, professor of physical chemistry in Cornell University, gave his lecture entitled "A Universal Law."[1]

The many chemists of the audience roundly applauded the claim that all branches of human knowledge are but portions of chemistry—mostly subordinate. They seemed highly to approve the idea of spelling "alchemy" with a double "l," and indeed the speaker's familiarity with things not generally called chemical went far to justify this notion.

The illustrations of the universal law were drawn mainly from that branch of chemistry commonly called biology, and those who still persist in calling themselves biologists instead of chemists accepted in good grace many a humorous and telling side remark.

When the lecture was over and the time for talking back came it seemed that most every one had something to say; but whether biologist or some other sort of chemist, each declared the meeting a great success, and since then has done much to make the "universal law" the universal topic.

W. J. Humphreys,

THE CONTROVERSY BETWEEN MATERIALISM AND VITALISM CAN IT BE ENDED?[1]

IN order that this discussion may be profitable, it must rest on an unequivocal meaning of some sort for the words "materialism" and "vitalism" It will, of course, be impossible to give definitions that will be altogether satisfactory to everybody, perhaps to anybody, even the writer. Every one may, however, be counted on to accept some definition *as a basis of the discussion*, if he thinks the question raised is worth discussing at all

Since my main desire is in behalf of clear thinking and remunerative work in biology to-day, my effort at defining the terms will specially regard present tendencies and methods in our science rather than lexicographical authority and historical usage, though the historical aspect must not be wholly ignored

By materialism I shall mean the belief that all biological phenomena may be completely explained by referring them to the material elements of which organisms are composed The term "mechanism" as used to-day, not in practical zoology, but in philosophical biology is, I think, exactly synonymous with materialism At any rate, I shall consider such to be the case.

It is less easy to formulate a definition of vitalism. 'I understand the term to mean the belief that organic phenomena can not be fully explained by referring them to the material elements of which organisms are composed, but that some-

[1] Address of the vice-president and chairman of Section F—Zoology.

thing not really belonging to the natural order, either explicit or implicit, is present in living things. The essence of the conception, whatever be its variety or form of statement, is that something absolutely new and novel came into the world when living beings came, and that this came as a special force, or principle, or factor—anything you have a mind to call it, so long as it is *not* material. A further essential to the conception is that this new thing is elemental, protean, once-for-all. It is not exactly the life itself of the organism. It is rather the informing, underpinning, ultimate motor, of life.

So far as a general discussion like this is concerned, there is no advantage in taking cognizance of a neo- or rejuvenated vitalism, beyond noting that the efforts in conformity with the modern demand for rigorous analysis is to limit, or locate this extra somewhat more definitely in, or among, the material substrata of organisms.

So much for definitions. I said a moment ago that the historical aspect of the subject must not be wholly ignored. All, however, that seems incumbent upon us in this quarter is to remind ourselves that the term materialism has cut a considerable figure in the philosophies of the schools, while the term "vitalism" has not. Further, to most traditional and vocational philosophers materialism as defined is a very naive, almost childish conception: while its adversary, vitalism, has little or no standing among philosophers. Its essential interests are abundantly cared for by professionals under other captions. The significant thing for us in this treatment of materialism and vitalism by philosophy is the evidence it affords that neither materialism nor vitalism stand up well as philosophical conceptions, under the fire of rigorous logical analysis and a highly developed dialectic. This circumstance can not go unheeded by any careful biologist, for whatever may be his estimate of the worth of metaphysical systems, he can not fail to recognize that every trained metaphysician carries a blade of analysis, and of offense and defense in intellectual encounter, that may well elicit the admiration and be the dismay of any ordinary man of science.

Now this slighting by formal philosophy of conceptions that biology makes much of when it attempts to be philosophic, ought to cause biologists to wonder if perchance their philosophizing is less happy, less trustworthy, than their achievements in science proper. This leads to where I may give my categorical answer to the question taken as the subject of the paper: The controversy between materialism and vitalism would end forthwith could both conceptions be recognized as only mile-stones along the road of progress, could they both be seen to contain truly living substance encapsuled by dead matter which must be left behind as crumpled exuviæ when the next stage of advance is entered upon. The controversy will not cease but will continue with increasing unfruitfulness so long as either side holds the truth it sees as absolute and all-sufficing.

To bring the real inwardness of the case home with force I am going to state it in a way that will at first seem extreme and harsh. ***Materialism is a lineal descendant in rational process of the basis of magic of certain ancestors of ours*** who, though far cruder than we are, were no less earnest of desire and of effort to understand nature and get on well with her. ***Vitalism is similarly descended from the animism of still other ancestors***, probably somewhat more recent and less crude, but no less earnest and sturdy than those with whom magic reigned.

This theory of the origin of materialism

and vitalism will probably appear not only harsh but ridiculous at first sight. The idea, it will be said, that many of the very foremost biologists of this hour are kindred, doctrinally, to magicians and occultists, is too absurd to merit consideration. To those who would dispose of the idea in this summary fashion because of a certain sense of injustice or of hurt pride, I would earnestly put the question, Are we truly evolutionists or are we not?

I am convinced that many of us, even biologists, who have never hesitated to accept evolution, do not see and feel its mighty importance when it comes to human traits that are particular and personal. Biologists more perhaps than other class need the regenerating touch of Bergson's "L'Evolution Créatrice." We need to recognize as we never have that evolution means indeed something new coming on every moment, and that since the new grows out of the old it can be neither wholly different from nor wholly alike that from which it came. We need further to see the vital meaning of the extreme probability in the light of myriad facts now constituting our biological knowledge that evolution is truly a universal principle, that is, that there is not a trait, physical or spiritual, of ours, that is wholly finished off and at a standstill. We are every one of us in every atom of our existence and at every instant on the move to some extent, up or down, forward or backward.

Where did all our science—not merely as to its formulation but as to its physical and psychical substratum, come from? Only a few thousand years ago our race not only did not possess a great body of knowledge of the world, but it was not scientific, as we now understand the term, either in mode of observing and thinking or in desire. Did our talent for science come to us as a gift from heaven, or has it grown by slow degrees from hundreds of impulses and influences spread over thousands upon thousands of years and over many lands and seas?

The theoretical answer to the question is on the lips of every one in an audience like this. Our talents came by the way of gradual growth, of evolution. Practically, though, we treat our knowledge much as did our forebears who believed their gifts came direct from heaven. Alongside this question let us ask another. What has become of all the mysticism, the fetishism, the magic, the animism, the divination, and the rest, so characteristic of every race and class of men outside of civilization? Is it reasonable, in the light of what we know about the course and laws of evolution to suppose that those psychical or other qualities that made our ancestors for generation after generation mystics should have left no trace in peoples under civilization excepting in the comparatively few professional mediums, clairvoyants and persons noted for their ignorance and superstition? Could we reasonably expect any modern whatever to be wholly cut off from any trait that was universal and of simply tremendous import in all his early ancestors?

I insist that there is a mighty vein of what makes mystics in the nature of every normal man and woman no matter how elevated a level of culture, or intellectual development he has reached. I insist further that we have not the slightest ground in facts at our command for supposing this element in man's nature can be eradicated and leave him civilized. The truth is that just so far as man feels or has sentiment, imagination, fancy, at all, by just so much is he mystically inclined. It is his intellect, his reason, alone that saves him from being a mystic indeed; and just as sure as any element of pure fancifulness gets into the essentials of a scientific, that is gen-

uinely rational, doctrine, that doctrine departs at once from the way of science and journeys on the way of mysticism and occultism.

This means, brought down to specific application, that search to-day after the "germ of life" in the sense in which this phrase has leaked out of biological laboratories and got into the popular mind is mystical no less certainly than was search after the philosopher's stone. It means that a certain heavily veiled hope being held out in certain biological quarters of the indefinite prolongation of life is the old search after the elixir of life and the fountain of perpetual youth, refined and modernized. It means that those biologists who by intense research on, and still intenser speculation about, a comparatively few "elements" and "substances" in the less well-known sections of the organic realm, seem to expect presently to find a hidden key that will unlock all or nearly all the mysteries of organic nature, are on the same quest with Dr. Faustus, the quest after ultimate knowledge and are doomed to failure and disappointment.

In other words, *the mighty tendency of the human mind to transcendental and mystical interpretations of the world which manifests itself among primitive peoples as fetishism, animism and magic, among more advanced peoples as idolatry proper, and among nearly all of the most advanced peoples as the supernatural element in religion, persists in our physical science, particularly in our biology, as materialism and vitalism.*

Stating the problem in this broadly generalized way commits us to a very large, difficult and important thesis. Obviously, to deal with more than a small fragment of it here is out of the question. In baldest essentials the truth can be stated thus: Materialism in common with magic consists (*a*) *in assuming the existence of material bodies to explain certain observed phenomena when such bodies do not in reality exist, or at least the existence of which is never proved observationally*, or (*b*) *in assuming that certain observed bodies possess qualities which explain phenomena when in reality no such qualities are possessed by the bodies, or at least are never observed directly*. Vitalism in common with animism consists *in assuming the existence of non-material, essentially extra-corporeal forces or principles to explain phenomena when such forces or principles are never proved to exist*. The sophisticated thinker and the untutored savage are alike in recognizing the mystery inherent in the universe, and they are further alike in their attempted explanations.

Just the fact that the universe is perpetually in the throes of "Creative Evolution" makes this mystery all-pervasive and unending. It is of the very essence of a living world. The wise man takes due account of this element of the incalculable, the unpredictable as a characteristic of the universe, particularly of animate nature, he is not driven thereby to despair of ever knowing anything, but on the other hand is preserved from the obsession of finding a "sufficient cause" for everything under the sun. He recognizes that the whole process is the one great, sufficient and final cause of all its phases, and with that conviction puts an end to all futile search for "complete explanations" and "absolute causes." The proximal causes, the workings of the great process, are, however, of absorbing interest to him. And they are of interest down to the smallest detail; nothing is insignificant, negligible, just because every minutest fragment is an integral and therefore influential part of the whole.

From this point of view, it can be readily

seen how futile is the attempt of materialism to find the "cause" of life in any one set of material elements, and how equally futile is the attempt of vitalism to find the significance of the whole in some intangible "force" Both fail to see that any set of processes taken as a whole and in its organic relation to the rest of the universe is its own final and only adequate explanation Each attributes to natural objects qualities which no single object or set of objects possesses—qualities which afford a complete "explanation" of another object Both attempt to explain everything in terms of "something else," and this in essence amounts to a denial of the reality of the organic beings which we actually see and deal with

WM E RITTER

LA JOLLA, CAL

INVESTIGATIONS OF THE CARNEGIE INSTITUTION[1]

WORK in the ten specially organized departments of research in the institution has gone forward during the year with increasing vigor and with increasing productivity All of these novel establishments may be said to have now passed the preliminary stages of organization, equipment and tentative experience, so that henceforth their efforts and resources may be still more effectively directed and applied Most of the departments have been strengthened during the year by additions to the staffs of investigators and by accessions to equipment and other facilities, some of which latter have come through the generosity of friends, who have thus shown their appreciation of departmental researches

But while the existing status of departmental affairs is in general highly satisfactory, it appears essential to again call attention to the fact that with present income and current economic conditions no further expansion of departmental appropriations can be expected It may be necessary, on the contrary, to curtail research in the departments in order to keep the aggregate expense of the institution within income It need not follow, however, that this prospective diminution in financial outlay will cause a corresponding diminution of productivity, for work of investigation, like work along other novel lines, is usually most costly in the preliminary stages

Referring to the current "Year Book" for interesting and instructive details in the reports of the directors of departments, some of the salient features of their activities are summarized in the following paragraphs

It is a maximum in the pursuit of physical science to proceed from the simpler to the more complex in any attempt to discover the relation among observed facts. In accordance with this maxim, the headquarters of the Department of Botanical Research are located in a desert area where the facts of plant life are exhibited, in general, in their simplest, though often extreme and highly specialized, relations. But even under these favorable conditions plant life presents problems whose solution requires aid from many sciences other than those which are commonly held to make up biology, and especially from chemistry, physics and meteorology Thus the researches of this department call for much collaboration and for a wide range of observation, experiment and determinate analysis

During the year the director of the department has continued his investigations on the water-balance of succulent plants, on the conditions of vegetable parasitism, on the variability in plant species induced

[1] From the report of the president

by chemical treatment of their seeds, and on the influences of climate on plant organisms. In collaboration with Professor Ellsworth Huntington, research associate of the department during a portion of the year, the director has begun a general climatological study of the region about Tucson, giving special attention to the factors and effects of the Santa Cruz and Asuncion river systems.

Dr. Cannon, of the permanent departmental staff, has given attention especially to his elaborate investigation of the root systems and habits of desert plants. For the purpose of extending the range of his studies in this fundamental subject he visited the Sahara Desert and will spend most of the year in that advantageous field for both comparative and direct observations. Some of the more important conclusions already established in respect to this inquiry are set forth in the director's current report.

Dr. Shreve, also of the permanent staff of the department, while occupied with the more general problem of the relation of plants to climate in the United States, has also carried on special investigations of the vital statistics of plants in the vicinity of the Desert Laboratory, of the vegetation in the Santa Catalina Mountains, and of the physiological characteristics of the lace-fern family of plants. In the first of these researches he has been aided by the collaboration of Dr. Livingston, who resigned from the staff of the department a year ago to accept a professorship in Johns Hopkins University.

Observations on the phenomena presented in the drying up of Salton Sea, and especially on the influx of vegetation over the bared strands and islands of this slowly retreating body of water, have been continued during the year. In this work a series of soil analyses of the strands has been secured through the cooperation of Mr. E. E. Free, of the Bureau of Soils of the U. S. Department of Agriculture.

Publications by members of the department issued during the year are shown in the list on pages 32-33 and in the bibliography of the "Year Book." Others in press are Nos. 131, 139, 141. One of these, No. 139, on the guayule, a desert rubber-producing plant of considerable economic importance, is the work of Professor Francis E. Lloyd, formerly a resident associate of the department, but now a member of the faculty of Alabama Polytechnic Institute.

So many converging lines of fruitful research are now being pursued by this department that it is difficult to summarize fitly its current progress. This duty must be accorded, in fact, as in all other cases, to the director of the department concerned, in his annual reports and in his more detailed publications. From the abstract scientific point of view the most interesting feature of this work is found in the introduction of statistical and other quantitative methods, whereby biology is now passing from the first to the next higher stage in the development of a science. From the more popular points of view the work in question is of special interest by reason of its bearing on the economics of plant and animal breeding and by reason of the light it is certain to shed on the laws of human heredity.

So large and so intricate a field of work calls for varied objects and subjects of experimentation and for the resources of many collateral sciences. Thus, studies of heredity have developed the necessity of certain investigations in physiological chemistry, and a small equipment for this purpose has been fitted up in a room of the main laboratory building and put in charge of Dr. R. A. Gortner. Similarly, for

studies of the changes which organisms undergo in dark caves and in deep waters, an artificial cave has been added to the basement of the laboratory, and the work of experimentation by means of this adjunct has been assigned to Dr A M Banta, whose early investigations in this line were printed by the institution some years ago in Publication No 67

In order to meet the increasing needs of the department for land for the cultivation of plants and the breeding of animals, the institution purchased in January, 1910, a tract of 21 acres of very desirable land lying about a mile east of the laboratory It may be noted also that Goose Island, in Long Island Sound, acquired for the department a year ago, has already been put to good use in experiments on plants and animals in a state of isolation

It is a source of pleasure to record that two friends of the department have shown their appreciation of the director's enterprise by gifts which will greatly aid him in the prosecution of his work one has supplied a wharf and a shelter house on Goose Island, the other has furnished funds essential to establish, near to but independently of the laboratory, an office for the collection and interpretation, under the direction of Dr Davenport, of data bearing on human heredity

The principal steps which have been necessary and in large degree preliminary in the development of the work of the geophysical laboratory are recounted with instructive particularity by the director in his report for the current year They are the steps required to pass from a merely descriptive knowledge of rock formation to a knowledge based on definite measurements. Briefly stated, these steps are four in number, namely: provision for correct temperature determinations over the entire range involved in the processes of rock formation, provision for like determinations of the chemical reactions of these processes, provision for precise microscopic, optical and crystallographic measurements, and provision for the quantitative applications of high pressures to rock masses and rock constituents

In supplying the desiderata just indicated for its own special work, the laboratory has already achieved results of prime importance also to many other fields of physical and chemical science Thus, two contributions of great import to general physics and chemistry have been brought out during the past year The first of these is a determinate extension of the scale of temperature measures from about 300° C to about 1,600° C This is a fitting supplement to the classic work on thermometry begun more than thirty years ago under the auspices of the International Bureau of Weights and Measures It must take rank, in fact, with the fundamental advances in the technique of thermometry The other contribution is a determination of the system of compounds which may arise in combinations of the three most important oxides entering into the composition of rocks, namely, silica, lime and alumina This system is of special economic interest, since it includes, among many other compounds, the hitherto much studied but baffling Portland cement The complexity of the investigations required to analyze this system is indicated by the facts that it involves the interaction of fourteen minerals and the formation of sixteen ternary eutectics, or substances whose melting-points are lower than those of the primary constituents

Many other important investigations are outlined in the director's report and the productivity of the laboratory may be inferred from his citation and review of twenty-five publications emanating from

the staff during the year It is of interest to note in this connection that researches from the laboratory find ready access for prompt publication through current journals both at home and abroad Many of these papers have already been published in German as well as in English and arrangements have been made during the year to maintain this doubly effective mode of publication

Six years ago, when the duties of the presidency were assumed by the writer, he deemed it desirable to visit at the earliest opportunity all individuals pursuing researches under the auspices of the institution It soon developed, however, that a speedy accomplishment of this task would prove quite impracticable, and it became essential to adopt a much more restricted program of activities in this direction Thus, while nearly all other departmental establishments of the institution have been visited by the president prior to the past year, his first visit to the Tortugas Laboratory was not made until June, 1910 Having already entertained very favorable, but somewhat indefinite, opinions concerning the wisdom of the choice of this locality for a marine laboratory, it is fitting to state that the extraordinary biological resources and the salubrity of the summer climate of the Tortugas group are so evident as to rouse the enthusiasm of any interested observer As pointed out by the director of the laboratory, the isolation even of these islands furnishes important advantages to the investigator In brief, the favorable impressions gained during the first visit in respect to the locality and in respect to the scientific spirit and possibilities of the establishment are only tempered by the present incapacity of the institution to give more liberal financial support to this department of work

Two emergencies seriously affecting the department and calling for prompt action have arisen during the year One is due partly to the gradual abandonment by the United States navy of the supply depot and wireless station at Tortugas, thus rendering communication between Key West and the laboratory less certain and frequent than hitherto The curtailment of this source of aid generously extended by the navy to the laboratory during the past six years has forced upon the department the necessity of providing better independent transportation than that afforded by its best boat, the *Physalia* One object, therefore, of the visit above referred to was to consider with the director the best way to meet this urgent need Accordingly plans and specifications for a 70-foot twin-screw boat were prepared during the summer, and on authorization by the executive committee, at its meeting of October 18, 1910, a contract for the construction of this proposed vessel was let October 31, 1910, to the Miami Yacht and Machine Co, of Miami, Fla, with the expectation that the contract will be completed July next

The other emergency arises from the damage to the laboratory caused by the hurricane of October 14–18, 1910 The extent of this damage is not definitely known at the present writing, but steps have been taken to get trustworthy details at the earliest practicable date, so that estimates of the expense required to restore the building may be ready for submission to the board of trustees before their next meeting in December

It is gratifying to note that the opportunities afforded for intensive research by the laboratory are so highly appreciated that applications for its privileges are already more numerous than can be granted. Each year since its establishment additions have been made to its equipment and the

director hopes that with some minor additions quarters may be found for fifteen or more investigators every summer During the past season twelve associates, one collector and one artist illustrator, in addition to the director, carried on work at the laboratory Of the investigators, nine returned to continue work begun in previous years, while two of the other three expect to return in 1911 Many researches are in progress, therefore, as may be seen by reference to the full reports of the director and his associates in the current "Year Book"

Of the publications of the department during the year, special attention should be called to the comprehensive monograph in three quarto volumes by Dr Mayer, on "The Medusæ of the World," issued as Publication No 109 of the institution Two other volumes, Publications Nos 132 and 133, containing short papers from the director and associates of the laboratory, are now passing through the press

Capital progress has been made during the year in the large and exacting undertaking which this department has so successfully started Work at the observatory in Argentina has gone forward at an unprecedented rate and with such a degree of thoroughness and completeness as to give assurances that this part of the enterprise will be completed within the next year Great credit is properly assigned by the director to the zeal and the industry shown by the resident staff of the observatory in thus completing, within so short a time and without lowering the highest standards of precision, an unparalleled amount of observational work The general success of this enterprise affords a forcible illustration of the superior effectiveness of a department of research which may proceed with its work intensively in accordance with carefully prearranged plans and organization of effort

While the supplementary observations of the positions of the stars are going forward in the southern hemisphere, arrangements for the final computations of these positions are proceeding at the Dudley Observatory, for the formidable task of observation must be followed by a still more formidable task of computation Preliminary to the grand catalogue of stellar positions projected by the department, there has been issued by the institution during the past year, as Publication No 115, a catalogue of 6,188 stars for the epoch 1900 This has already assumed first rank among catalogues of precision and the demand for it indicates that a second edition may be called for before the larger catalogue is completed In response to a demand from other astronomers and in view of the needs of his own work, the director has published also, through the Dudley Observatory, a "List of 1059 standard stars for 1910"

Although this laboratory has been occupied less than two years and is not yet fully equipped, it has already produced contributions of fundamental importance to our knowledge of the chemistry, physics, physiology and pathology of nutrition Its experience, like that of all the laboratories of the institution, affords an impressive demonstration of the productivity attainable by concentrated effort along determinate lines of research Construction and installation of additional equipment, the prosecution of investigations, and the publication of results have gone forward simultaneously during the year.

One new calorimeter has been completed, another partly constructed, and various auxiliary apparatus for use with these and the earlier equipments have been supplied Similarly, respiration apparatus for men,

respiration apparatus for dogs, and many improvements in the calorimeter section of the laboratory have been made. Several pieces of apparatus have been acquired also by purchase abroad, and the efficiency of the machine shop has been improved by the addition of a precision lathe.

The investigations under way at the laboratory and outlined in the director's report are too numerous and too technical to permit further abstract or paraphrase. It may suffice here, therefore, to cite one of the most important of these investigations in which decided progress has already been made, but which may yet require many years to complete, namely, the nature and meaning of metabolism in diabetes. In the researches on this recondite problem the director has thus far had the good fortune to enlist the active cooperation of Dr. Elliott P. Joslin, through whose aid especially it has been possible to use the laboratory's apparatus in detailed observations and measurements of a number of diabetic patients during the past two years.

The preliminary results of the research just referred to were regarded as so important as to justify prompt public announcement, and they have accordingly been printed during the year in Publication No. 136. Interest in the laboratory and its work is now so widespread that another volume, describing in detail the respiration calorimeters and their applications, by the director and Mr. Thorne M. Carpenter, has been issued as Publication No. 123. Many shorter publications from members of the research staff have appeared during the year in current journals and in the proceedings of learned societies.

The rapid growth in equipment and facilities and the equally rapid progress in the production of capital results from the researches at this observatory are at once sources of surprise and gratification to the astronomical world. Work during the past year has gone on with little diminution of vigor, although illness of the director has forced him to relinquish his activities for a considerable portion of the time. He has recently gone abroad for a season and the departmental report for the past year has been prepared by Mr. Walter S. Adams, now acting director of the observatory.

The work of this establishment is now so extensive and so varied that it is somewhat difficult to summarize even in its salient aspects. In addition to the observatory proper, with its four principal telescopes and much auxiliary equipment on Mount Wilson, there are the physical laboratory and the instrument shops at Pasadena, along with special divisions devoted to the work of computations and construction respectively. To become conversant, therefore, with the complexity of activities of this department, one must read the somewhat lengthy but relatively condensed annual reports of the director.

By way of equipment several large pieces of apparatus for the new tower telescope, for the 60-inch telescope, and for the 100-inch grinding machine have been made at the shops. The towers for the new 150-foot tower telescope, begun a year ago, are now finished along with the well, 75 feet deep in the rock below, which forms a part of the telescope tube of this novel instrument, now essentially complete except for its spectroscopic attachments still under construction at the shops. Some preliminary trials made recently with this instrument indicate that it will fulfill the sanguine expectations entertained in respect to its capacity.

At the time of the annual meeting of the board of trustees a year ago "The Monastery," a wooden building on Mount Wilson supplying quarters for the resident members of the observatory staff, was com-

pletely destroyed, along with a considerable number of books and other valuable property, by fire This building has been replaced during the year in somewhat enlarged form by a reinforced concrete structure

Progress has been made during the year in the details of designs for the proposed 100-inch or "Hooker" telescope, for which Mr J D Hooker, of Los Angeles, made a substantial gift to the observatory some years ago This work has been in charge of Professor Ritchey, whose construction of the 60-inch reflector has proved so signally successful After repeated trials and failures to make a satisfactory disk the contracting firm at St Gobain, France, have quite recently renewed the hope that a disk they now have annealing may meet the exacting requirements set by the astronomers

Allusion has already been made in an earlier part of this report to the meeting of the International Union for Cooperation in Solar Research held at the observatory during the week of August 29 to September 4 of the current year An outline of the proceedings of this meeting, which was of peculiar interest to the observatory staff, is given by the acting director at the end of his report In spite of the difficulties of access to the observatory site, this meeting was regarded as the most important held by the union Opportunities were afforded the visiting astronomers and physicists to inspect the entire establishment and to test especially the efficiency of the telescopic apparatus Their appreciation of these opportunities and of the optical perfection of the telescopes, particularly of the 60-inch equatorial reflector, is a source of keen encouragement to the observatory staff

Attention is invited to the interesting account given in the departmental report of the numerous investigations now under way at the observatory and in the physical laboratory at Pasadena They are so effectively summarized in this report that any restatement appears superfluous

No department of research in the institution is conducting work which is at once so obviously practical and so obviously theoretical as the work of the department of terrestrial magnetism Every one acquainted with the daily use of the compass in exploration, in surveying, and in navigation recognizes the practical utility of a magnetic survey of the earth But those who recognize that any utilitarian results may come from a deeper knowledge of the earth's magnetism and its cosmic connections are at present very limited in number Nevertheless, the history of science warrants a confident expectation that the latter results will ultimately prove to be of much greater value than the former

The more striking events of the year in this department refer naturally to the non-magnetic ship *Carnegie*, which was off on her first cruise at the close of the previous fiscal year She was then at Falmouth, England, where her determinations of the magnetic elements were compared with independent determinations made at the permanent magnetic observatory of that port She proceeded thence, November 9, 1909, to Funchal, Madeira, thence to Hamilton, Bermuda, and thence, under tempestuous conditions which proved her seaworthiness, to Brooklyn, N. Y, where she arrived February 17, 1910 Here she had her copper sheathing applied by the constructors, as required by their contract, and was overhauled and refitted for a three years' circumnavigation cruise It is a pleasant duty to report that in all essential respects this vessel has proved more effective than was anticipated It has been demonstrated that even in rough weather

the three magnetic elements (declination, dip and intensity) may be determined with a precision little short of that attainable in a fixed observatory Thus she was able to discover on her first cruise errors of unexpected magnitude in the best sailing charts of the north Atlantic, and she is certain to attain at least an equal degree of precision in all future ocean work By crossings of her own tracks and by connections at all available ports having magnetic observatories it will be practicable to exclude the possibilities of any important errors in this work

Similarly satisfactory progress has been made also in the land work of the department during the year The expedition in Africa, from the Cape to Cairo, undertaken by Dr Beattie and Professor Morrison as temporary associates, was completed early in the year, a total of 348 stations having been occupied Mr Pearson, field observer of the department, continued work in Turkey in the early part of the year until relieved by Mr Sligh, who extended the work to Palestine, Syria, Arabia, Mesopotamia and the islands of Rhodes and Cyprus Up to the end of July of this year these two observers had occupied a total of 47 stations Another observer, Mr Stewart, left Washington early in June to begin extensive work in South America, proceeding in the launch *El Imán*, provided especially for work along the Amazon and its tributaries Additional observations are reported also from Canada and from various European countries in which initial determinations or instrumental comparisons have been made

The office work of the department has gone forward with corresponding productivity, the large volume of computations required being kept closely up-to-date The preparation for collective publication of data obtained by the department on land and on sea is now well advanced, although many of these data have been already furnished for use by hydrographic offices and other national and international bureaus Much critical attention must be devoted by the office staff to the inspection and perfection of instruments and auxiliary appliances By the aid of a skilled mechanician and a shop now attached to the department it has been practicable to attain a degree of instrumental perfection and a degree of economy in cost not hitherto equalled in this kind of work

About fifty research associates have carried on investigations under the auspices of the institution during the past year, either by aid of grants made directly to the individuals concerned, or by aid of grants made to organizations like the American Schools at Athens and Rome, or by cooperation with our departments of research In general, each of these associates has been in collaboration with one or more colleagues or assistants, so that the total of those contributing to this work has been upwards of one hundred investigators The range of their investigations embraces sixteen distinct fields of research, namely archeology, astronomy, botany, chemistry, geology, geophysics, literature, mathematics, metallurgy, meteorology, paleontology, philology, physiology, political science, terrestrial magnetism and zoology Reference must be made, therefore, to the reports of individual investigators and to the general bibliography, to be found in the current "Year Book," for a fuller account of the fruitful activities in this branch of the institution's work It should be observed, however, that existing and prospective economic conditions, elsewhere referred to in this report, will probably require curtailment in this branch of work in the near future.

CHARLES HUGH SHAW

THE subject of this sketch was born near Delaware, Ohio, July 14, 1875 He was educated in the public schools of Delaware County and city and in Ohio Wesleyan University located hard by He received the degree of Ph D from the University of Pennsylvania in June, 1900, at the age of twenty-five

Shaw very early exhibited a strong leaning to the natural sciences and while still in the public school he became thoroughly acquainted with the local flora In college under the direction of Dr E G Conklin, at that time professor of biology in Ohio Wesleyan, he was appointed an assistant charged with the collection and preservation of a complete herbarium of that flora Under the inspiration of the same instructor he mastered the elements of zoology, and became saturated with the principles of organic evolution When Dr Conklin was called to Northwestern University his successor was a botanist and Shaw was employed to continue the instruction in zoology, which he did for two years with great credit to himself

Immediately after his graduation in 1897, he took up the advanced study of botany at Pennsylvania under Professor J M Macfarlane, whom he had met the previous summer at Woods Hole While carrying on his graduate studies and for several years thereafter he gave instruction in biology at Temple College The year he received his doctorate he accepted a place also in the faculty of the Medico-Chirurgical College of Philadelphia Here he was promoted through the various ranks and became full professor of botany in 1907 Resigning his place in Temple College in 1903, he became professor of biology at Ursinus College near Philadelphia, and continued to hold the two positions, that at the Medical College and at Ursinus, for four years Upon attaining full rank at the Medical College he gave up the work at Ursinus, and just a few months before his death he resigned at the Medico-Chirurgical to accept an assistant professorship in plant physiology at the University of Pennsylvania

Dr Shaw was a field botanist of the first rank He had collected and studied plants over many parts of the virgin land of the United States, Canada and Europe The summer of 1899 he spent with Goebel in Munich and the summer of 1906 with Flahaut in Marseilles The summers of 1904, '05, '07, '08, '09 and '10 he conducted botanical excursions to the Selkirks and Canadian Rockies, and it was while on the last of these that he met his death by drowning in Kinbasket Lake, B C, July 30, 1910

Shaw's broad grasp of botanical science is indicated by the following diverse titles among his published studies "Cleistogamy in Polygala," "Embryology of the Papaveraceæ," "Development of Vegetation in Morainal Depressions," "The Causes of the Timber Line," etc During recent years his interest centered more and more in ecological and physiological problems, and at the time of his death he was engaged on some fundamental investigations bearing on the influence of climate and of different light waves on plants He left a large number of instrument readings on the rate of evaporation, temperature, humidity and insolation obtained at widely different altitudes and exposures in the Selkirks which doubtless will be given to science in due time

While he was an original and clear thinker on scientific problems, Shaw was even more successful as a teacher Professor George Palmer a few years ago emphasized four essential qualities of the successful teacher (1) knowledge, (2) vicariousness, i e, the ability to take the point of view of the student, (3) clear exposition and (4) enthusiasm or the ability to inspire I have often thought of Dr Shaw as embodying these four qualities in a very high degree His knowledge was not encyclopædic, but was broad and fundamental He cared not for the out-of-the-way facts, but rejoiced in the large principles of his science It was for this reason that he advocated the choice in elementary teaching of only such topics as would rouse the student to make original observations and to draw independent conclusions His views on this principle in

teaching were presented in SCIENCE under date of September 11, 1908.

Shaw's ability to see a subject from the student's standpoint was a natural consequence of a sympathetic nature, a youthful and buoyant spirit and his simple-mindedness. There was nothing subtle about his mind and nothing covert about his nature. He was the soul of candor.

Clear exposition depends necessarily upon a clear grasp of a subject in the essentials. It depends also on sharpness of memory pictures and upon strong language powers. In all these Shaw excelled. Facts seemed to fall into his mind in their proper relationship almost without effort on his part. The knitted brow was not a characteristic of his face. Effort to clear up a thought was evinced rather by a wide-open movement of the eyes as if merely to take in all the elements of a situation and the answer was given immediately all were included. His memory for names and for essential facts was almost unfailing. The only fault in Shaw's exposition came on the expressive side. He gave the impression often of hesitation when the real trouble was not lack of *a* word, but lack of *his own word*. He was not content with the usual mode of expressing a thought. The truth to him was so engaging that it always seemed to require a special search for a word good enough to give it utterance. However, this fault, if fault it may be called, was seldom a hindrance. There was a certain clarity of thought in his very manner and his obvious sincerity won instant attention. He became quite a favorite in many places about Philadelphia as a popular lecturer.

Shaw's emotional side was as strong as his intellect. Truth for him was not merely the solution of a puzzle, nor merely beautiful, it was a sort of blessing. He cared most for that knowledge which had meaning for the largest life of the human spirit, but that meaning for him could not be expressed by any dogma, he must find it for himself. It was this quality—this deep appreciation of truth—that made his teaching inspiring. His class room was popular because through his clear vision his students got a new insight into nature, the universe, themselves.

Few men have a stronger love of nature in all her moods than had Charles Shaw. Since the age of nineteen, when first he saw the mountains he had spent some time almost every year among them. The Blue Mountains, Catskills, Adirondacks, White Mountains, Selkirks, Rockies, Alps he knew thoroughly. Nearly always he was accompanied by a party of students who learned to camp and to be content under the simplest of conditions—a shelter, a fire, a blanket. They acquired self-reliance and hardihood. They caught his love of life in the open.

Large and strong of body, Shaw was large and strong in his personality. He and I were classmates in college, were post-graduate students together and had been intimate friends ever since. He was the cleanest man I ever knew, and was the best illustration I could give of the beatitude, "Blessed are the pure in heart."

On Christmas day, 1901, Dr. Shaw was married to Miss Blanche Jackson at her home in Waterloo, Iowa. This union had the greatest influence in developing him to full, noble stature. Two most promising children are left with Mrs. Shaw. J. R. MURLIN

THE UNIVERSITY OF ILLINOIS MOVEMENT FOR A UNIVERSITY CONSTITUTION

THE first step toward carrying out the plan devised by President James of forming a constitution for the University of Illinois was taken on Monday evening, March 13, 1911.

President James on that evening met with a committee of the senate consisting of fifteen members of the faculty and outlined to them what he conceived to be the situation, the underlying problems and the possibilities. After speaking of the organization of foreign universities, including those of England and Prussia, President James called the committee's attention to the changing and shifting conditions in the universities of the United States and particularly in the states immediately surrounding Illinois.

In Iowa a new method of administration of the State University and other state schools was entered upon this last year The boards of regents were abolished and the three state institutions are being governed by one board of education, the members of which are appointed by the governor In Kansas a similar law has just been passed and awaits only the signature of the governor to make it effective

If such radical changes are to be made it would seem wiser that they should come upon the initiative of the universities themselves rather than from politicians At any rate it should be done only after a careful study of the whole situation

This senate committee at the University of Illinois is entering therefore upon an auspicious work It is expected that it will be engaged at least one year before a report will be prepared

The members of the board of trustees of the university are much interested in this undertaking for they realize the need of a definition of their duties and powers and they will be only too glad to have a statement made of the relations of the board to the state government, on the one hand, and the relations of the board to the university, on the other hand

Four leading members of the board—President William L. Abbott, Mr Fred L Hatch, for fifteen years a member of the board, Mrs Mary E Busey and Mrs Laura B Evans—were present at this initial meeting and gave it their hearty approval

The fifteen members of the senate committee that is to carry on this important work during the coming year represent (either as graduates or as former instructors) some eighteen leading universities, three law schools, three technical schools, two colleges, all in the United States and five foreign universities and technical colleges The members of the committee are the following Professor Henry Baldwin Ward, chairman, Professor Arthur N Talbot, Professor Herbert W Mumford, Assistant Professor James H Pettit, Assistant Professor Henry L. Rietz, Professor Frederick Green, Professor Ernest R. Dewsnup, Professor Julius Goebel, Mr Charles H Mills, director of the School of Music, Mr Phineas L Windsor, librarian, Professor Boyd H Bode, Associate Professor Wm A Oldfather, Professor Frederick M Mann, Professor Edward S Thurston, Mr Charles M McConn, secretary

SCIENTIFIC NOTES AND NEWS

DR HENRY PICKERING BOWDITCH, professor of physiology at the Harvard Medical School for thirty-five years, eminent for his contributions to this science, died on March 13, in his seventy-first year

DR WILLIAM H NICHOLS, president of the eighth International Congress of Applied Chemistry, was the guest of honor at a dinner tendered him by twenty-two members of the executive and sectional executive committees of that congress on March 7, at the Engineers' Club, New York City The occasion for this dinner was Dr Nichols' departure on an European trip He will visit Italy, Austria, Germany, France, Belgium, Holland and England, and to the chemists of these countries he will personally carry invitations to the congress

LIEUTENANT-COLONEL DAVID PRAIN, F.R.S., director of the Royal Botanic Gardens, Kew, has been elected a member of the Athenæum Club

WE learn from *Nature* that Professor H E Armstrong, F R S, has been nominated the delegate of the Royal Institution at the celebration of the centenary of the Royal Frederick University of Christiania, and Sir James Crichton-Browne, F R S, as delegate at the celebration of the 500th anniversary of the University of St Andrews

PROFESSOR JOSEPH P IDDINGS recently delivered two lectures before the geological department of the Johns Hopkins University on "Some Problems in Rock Classification"

DR. H. E. IVES, of the research department of the National Electric Lamp Association, delivered an illustrated lecture on "Color Measurement" at a well-attended open meet-

ing of the Case Chapter of the Society of Sigma Xi, in the physics building of Case School of Applied Science, on the evening of February 23, 1911

Mr. M N Baker, editor of the *Engineering News*, gave a lecture on March 16, before the engineering school of the University of Vermont on "The Engineer and the City"

The American Scenic and Historic Preservation Society in cooperation with the American Museum of Natural History, arranged at the museum, on March 23, an illustrated lecture on "The Physical History of the Grand Canyon District," by Professor Douglas Wilson Johnson, of Harvard University

Professor G W Ritchey, of the Solar Observatory of the Carnegie Institution at Mount Wilson, will give a lecture on "Celestial Photography," at Harvard University, on March 28 The sixty-inch mirror of the observatory is the work of Professor Ritchey's hands, and the lecture will be illustrated by recent photographs taken with that instrument

The nineteenth "James Forrest" lecture of the Institution of Civil Engineers, will be delivered on June 28, by Dr F H Hatch, his subject being "The Past, Present, and Future of Mining in the Transvaal"

The Huxley lecture at Birmingham University is to be delivered by Professor Henri Bergson, lecturer on philosophy at the University of Paris

The trustees of Columbia University have voted that the head professorship of physiology in the College of Physicians and Surgeons be named the Dalton professorship, in honor of the late Dr John C Dalton who held the chair of physiology from 1860 to 1883, and was president of the college from 1884 to 1889 The professorship is now held by Dr Frederic S Lee

We regret to record the death, on March 1, of W G W Harford, at Alameda, California Mr Harford was eighty years of age and had long been associated with the University of California, the Academy of Sciences and other institutions of research as collector, curator, etc, and was a special associate of the late Dr A Kellogg, in his botanical expeditions He published an early report on collections made in Alaska under the supervision of Professor George Davidson, and was especially interested in conchology

Mr E E Wilson, formerly assistant in the radiography department of the London Hospital, died on March 2, as the result of disease contracted by exposure to Rontgen rays

The formal opening of the Chemists' Building, 50–54 E Forty-first Street, New York City, took place on March 17, 18 and 19 At the dedication exercises the program was as follows

Address by the president of the Chemists' Building Company, Dr Morris Loeb

Address by the honorary president of the Eighth International Congress of Applied Chemistry, Dr Edward S Morley

Address by the president of the American Chemical Society, Professor Alexander Smith.

Letter from the president of Johns Hopkins University, past president of the Society of Chemical Industry

Address by the president of the American Electrochemical Society, Professor William H Walker

Address on Chemical Education by Professor Wilder D Bancroft

Unveiling of Rumford Memorial by Professor Frank Wigglesworth Clarke

Address by the president of the Chemists' Club, Dr Russell W Moore

We hope to publish a full account of the building, of the exercises and of the scientific program of the following days

A congress of technology which will give in the papers to be presented a record of the place and practical achievements of science in modern life, will be held in the buildings of the Massachusetts Institute of Technology in Boston, on April 10 and 11 The sessions will be open to the public This occasion also marks the fiftieth anniversary of the granting of the institute's charter, and the congress is therefore in part a celebration of this anniversary During these fifty years the world has seen that "advancement, development and practical application of science in connection

with arts, agriculture, manufacture and commerce," which the institute was organized to promote The institute has trained a number of men who are now in the very front rank of science In addition to this its former students are to be found in positions of power and responsibility in every state of the union, engaged in the work of developing mines, opening up the country by means of railroads, applying scientific methods to the problems of transportation, power production and distribution, advancing chemical industries, conserving the public health and contributing in countless other ways to the increase of the nation's wealth This practical application of science to the affairs of life will be surveyed and described, as also the conditions and problems of groups of allied industries, in a large number of papers by alumni and members of the faculty of the institute The papers will cover such general subjects as architecture, business administration, economics, public health and factory sanitation, industrial organization and training, power production and distribution, materials and manufacturing processes, reclamation of arid lands. The subject of scientific management will be presented from many points of view, as it may affect railroads and various manufacturing industries Among the speakers will be:

David Van Alstyne, '86, Allis Chalmers Co, Milwaukee, Wis

Henry G Bradlee, '91, Firm of Stone & Webster, Boston

Harvey S Chase, '83, Certified Public Accountant, Boston

Samuel M Felton, '73, President, Chicago Great Western Railroad, Chicago

Louis A Ferguson, '88, Second Vice president, Commonwealth Edison Co, Chicago

Walter C Fish, '87, Manager, Lynn Works, General Electric Co, Lynn, Mass

John R Freeman, '76, Consulting Engineer, Providence, R I

Charles Hayden, '90, Hayden, Stone & Co, Bankers, New York and Boston

Henry M Howe, '71, Professor of Metallurgy, Columbia University

Edwin O Jordan, '88, Professor of Bacteriology, University of Chicago

Walter H Kilham, '89, Architect, Boston

James P Munroe, '82, Executive Director, Boston 1915, Boston, Mass

Frederick H Newell, '85, Director, U S Reclamation Service

Robert H Richards, '68, Professor of Mining Engineering and Metallurgy, Massachusetts Institute of Technology

Albert Sauveur, '89, Professor of Metallurgy, Harvard University

George C Whipple, '89, Consulting Engineer, New York City

Willis R Whitney, '90, Director, Research Laboratory, General Electric Co, Schenectady, N Y

Salmon W Wilder, '91, President and Treasurer, Merrimac Chemical Co, Boston, Mass

C E A Winslow, Associate Professor of Biology, College of City of New York

THE expedition, recently sent out by the American Museum of Natural History and the New York Zoological Society, to Lower California, under the leadership of Dr Charles H Townsend, has been successful in capturing six young California sea elephants (*Macrorhinus angustirostris* Gill), on Guadalupe Island These specimens, the first ever captured alive, were sent from San Diego, California, on March 7, and arrived at the New York Aquarium on March 13, in excellent condition after their six-day trip For transportation they were crated separately and shipped by express without food or water en route Although not more than nine months old the average weight of these animals is about 250 pounds, and the length four and one half to five feet The adult males reach a length of more than twenty feet The species, which is distributed among the small islands of the southern and Lower California coast, is now verging toward extinction and very little is known of its life history or habits The common name of the species is derived from the fact that the male possesses a protrusible snout or proboscis In the young males now at the aquarium this is only slightly developed

THE path taken by Halley's comet in 1909–10 is to be shown in a series of photographs now being prepared by the committee on comets of the Astronomical Society of America, of which Professor George C Comstock,

of the University of Wisconsin, is chairman. The committee desires to secure a collection of material which will show by photographs the history of the comet from its first appearance until it was no longer visible even to the most powerful telescopes. The committee is requesting every astronomer who possesses any photographs of the comet to cooperate with them in making this history complete. The photographs used will be of four kinds: those possessing conspicuous technical excellence, those of good quality but having slight defects, those presenting obvious technical defects, and those obtained with small cameras by unskilled observers. As many as possible of the photographs used will be of the first class, but when it is necessary to make use of some of inferior excellence in order to avoid gaps in the history this will be done.

UNIVERSITY AND EDUCATIONAL NEWS

The appropriations for the U. S. Bureau of Education for the fiscal year ending June 30, 1912, show an increase of $7,600 over the appropriations for the current fiscal year, as follows: For the investigation of rural education, industrial education and school hygiene, including salaries, $6,000, one clerk at $1,600. The total specific appropriations for the bureau are as follows: Salaries, $72,800, library, $500, collecting statistics, $4,000, distributing documents, $2,500, printing annual report, $25,000, education of natives of Alaska, $200,000, reindeer for Alaska, $12,000.

The legislature of the state of Utah, during its recent session, made an appropriation of $300,000 to the State University for the construction of the main building of the institution. This building is to house the general library, the art gallery and the administrative offices. The legislature also passed a bill which has become a law, putting the support of the university and the agricultural college on a permanent financial basis by providing that these two institutions shall receive annually 28 per cent. of the income of the state derived from a 4½ mills tax. This 28 per cent. was divided between the institutions as follows: 64.43 per cent. to the university, 28.34 per cent. to the agricultural college and 7.23 per cent. to the branch normal school, a separate institution affiliated with the university. On the basis of present assessed valuations the annual income of the university for general maintenance is about $200,000. New buildings and other constructions are to be provided by special appropriations.

The legislature of Indiana, which adjourned on March 6, appropriated nearly $200,000 to Indiana University for the next biennium. This appropriation includes $150,000 additional maintenance, $35,000 of which is for the Graduate School, and $50,000 for the Medical School, for the maintenance of the Long Hospital.

According to the daily press a graduate of the Philadelphia College of Pharmacy whose name has been withheld, has offered to donate $1,000,000 toward the erection of a comprehensive group of three buildings, one of which shall be specially devoted to research work, for the institution. He stipulated that the building shall be on the Parkway on a site provided by the city. Mayor Reyburn divulged this fact in discussing his plans for making the western end of the Parkway, between Logan Square and Fairmount Park, a great center for Philadelphia's educational, engineering, scientific, historical, art and research organizations.

Mrs. Benjamin Hicks, of Old Westbury, N. Y., has bequeathed $100,000 to Swarthmore College.

Columbia University has received the sum of $693,000 from the executors of the estate of the late Mr. George Crocker, for the establishment of the Crocker Cancer Research Fund. It is understood that the remainder of the bequest is under litigation.

We are requested to state that assistant professorships of physiology, anatomy and bacteriology and pathology are to be filled in the Philippine Medical School. Information respecting the positions may be secured by addressing the Chief of the Bureau of Insular Affairs, War Department, Washington, D. C.

THE School of Engineering at the University of Pittsburgh, announces that Mr Morris Knowles, C E, will take charge of the course in sanitary engineering and public health This course will be developed in cooperation with the medical school of the university and the departments of health of the city and state The students will have a year's practical work along this line during their four years' course

THE board of trustees of the University of Illinois in its annual meeting on March 14, made the following appointments and promotions George Alfred Goodenough, associate professor of mechanical engineering, of the university was promoted to be professor of thermodynamics Professor Charles Russ Richards, dean of the College of Engineering, University of Nebraska, professor of mechanical engineering in charge of the department Professor Richards succeeds, as head of the department, Professor L P Breckenridge, who two years ago relinquished his office to take up work at Yale University Mr Burt R Rickards, of Columbus, Ohio, who has been for some three years chief of the laboratories of the Ohio State Board of Health, was appointed associate professor of municipal and sanitary dairying in the Agricultural College

DISCUSSION AND CORRESPONDENCE

LARVAL SPECIES

IN his recent review of Theobald's last volume on the mosquitoes Dr. E P Felt emphatically condemns the founding of species, or of a classification, on larval characters.[1] Dr Felt has a right to his opinion, but his remarks are so incomplete that they do not fairly present the question at issue. In the case of the Culicidæ, as in the many others that might be cited, there were causes which led logically to such a course First of these was the fact that certain species of mosquitoes could not be distinguished in the imago state, while they showed very marked differences in the larval condition This led naturally to the founding of species on the early stages and Dr. Felt himself was the first to take this step He has been amply justified by the fact that, in spite of diligent study with abundant material, no tangible characters for separating the imagos have been found It should be added that a study of the male genitalia has revealed corresponding differences, equally marked with those of the larvæ There can therefore be no question that the species indicated on larval characters really exist in nature Since then a considerable number of species have come to light which are only separable on characters of larvæ and male genitalia

Under such circumstances two courses are open to the systematist who will not recognize larval characters, neither of which, in our opinion, is scientific The most convenient is to ignore the true condition and adhere to the concept of species on the basis of well-marked differences in the imagos, the other is to admit the species indicated by the larvæ and draw up descriptions from the indistinguishable imagos To designate, as specific, individual differences due to variation, as Theobald has done in the case of *Aëdes fitchii*, *A abfitchii* and *A subcantans*,[2] only obscures the subject. We do not advocate the founding of species on larval characters as a general practise and we think that Dr. Felt expresses needless alarm on this account Under the special conditions indicated above and in similar cases we not only consider the founding of species on larval characters justified, but unavoidable Furthermore, if the mosquitoes are considered from an economic standpoint (and we are constantly told that this is the primary reason for their study) a knowledge of the larvæ is fully as important as that of the imagos

But, Dr. Felt's criticism in his approval of Theobald's position is mainly aimed at our paper on the classification of the mosquitoes by larval characters[3] He chooses to ignore the fact that we have since published a classification of the imagos, which, in the main, is

[1] SCIENCE, N S, Vol XXXIII, pp 150–151

[2] "Monogr. Culicidæ," Vol 4, 1907, pp 319, 321

[3] "The Larvæ of Culicidæ Classified as Independent Organisms," *Journ N Y Entom Soc*, Vol 14, 1906, pp 169–230, pl 4–16

in accord with that we had indicated with larvæ[4] It is now clear that the old classification, employing the relative length of the palpi in the two sexes as a primary character, is not a natural one It is true that the length of the palpi indicates, in a general way, the evolutionary state of the species The forms with the long palpi are the more primitive ones, reduction having occurred first in the female, where, on account of the feeding habits, they were most in the way, and then in the male The forms with the palpi shortened in both sexes are therefore evolutionally the highest

Unfortunately for any system based on this character, the reduction of the palpi has taken place independently at different points and on this account the forms with the palpi short in both sexes can not be associated, as was formerly done Dr Adolpho Lutz was the first, in 1904, to subordinate the palpi and to outline a natural classification Theobald has adopted this classification as the frame-work for his complicated scale-character system We have found good reason to go still further than Dr. Lutz and discard the palpi for even generic limits Aside from this it will be found, when the errors and weak points are eliminated from both, that the classification of Dr Lutz, and the one we formulated on larvæ alone, agree very closely Furthermore, the genitalia, when understood, indicate the same grouping It seems that the question of stability strongly influenced Dr. Felt in his criticism We venture to point out that only by attacking problems from new points of view can we progress. There are no fences in true science

The further salutary effect of the study of the larval characters has been to establish a more exact and homogeneous concept of generic values. The best example is the genus *Culex* Formerly the most heterogeneous elements were united under this name, and with those who work with the superficial characters of the imagos alone this is still the practise. Thus, even in the last volume of his work, Theobald associated wholly unrelated forms in this genus, while, on the other hand, forms which should be included are removed and scattered through the system on account of trifling differences in the scale vestiture We believe that an impartial and careful study of the Culicidæ from all points of view will show that we were justified in overturning the crude ideas on which their classification was based and that this was brought about through our study of the larvæ as organisms unrelated to their adults We believe that the names founded on larvæ are valid and should be given due priority The characters used are in many cases more positive and reliable than those found in the adults and are further of more evolutionary importance than those heretofore used in classifying the adults

THE GERM-CELL DETERMINANTS OF CHRYSOMELID EGGS

THERE lately appeared in these columns under a title similar to the above, an article[1] by Dr R W Hegner dealing with a paper of mine[2] in which I had questioned his use of the term "germ-cell determinants" as applied to the granules of the pole disc of chrysomelid eggs As I do not quite agree with Hegner's interpretation of my position, I take this opportunity to make a more explict statement of my point of view

To my mind, a cell or tissue *determinant* suggests or implies a physiological activity that, to use a crude illustration, resembles the physical action of a dye upon impressionable metal Thus a germ-cell determinant would be something that stamps the undifferentiated cells arising from the cleavage nuclei with a specific germinal or reproductive property.

I have given evidence that what he calls "germ-cell determinants" are in all likelihood merely a part of the food stream from the nurse cells, and this Hegner admits is no

[1] R W Hegner, "The Germ cell Determinants in the Eggs of Chrysomelid Beetles," SCIENCE, Vol XXXIII, No 837

[2] *Biol Bull*, Vol XVIII, No 4

doubt correct As far as I have been able to determine, when they first enter the egg, these granules differ in no wise from those in other parts of the food stream that develop into yolk spherules

Now the early developmental features of the germ cells in this species point not so much to a process of active differentiation as one of passive isolation, which results in the pole cells retaining or preserving the reproductive potentialities of the cleavage nuclei, the pole-disc meanwhile serving as food material for the pole cells which "as a result of this special kind of nutrition undergo a peculiar method of metabolism which differentiates them from the somatic cells"—just as a certain kind of food is necessary for the early growth and development of a child, but is by no means the cause of its becoming a man instead of an ape H L WILMAN

THE PYTHAGOREAN THEOREM

DR NORTHRUP's article[1] is not a proof of what is sometimes—perhaps incorrectly—called the *Pons asinorum* unless it be shown *experimentally* that the kinetic energy of a body is the sum of its energy of translation and of rotation The deduction, however, of this theorem of energy from the fundamental propositions of mechanics depends on the law of vector superposition, the mathematical expression of which involves the Pythagorean theorem In general it is not economical to derive mathematical propositions from experimental physics, moreover, the process fails to bring out that difference between mathematics and physics which is shown, for example, in Hilbert's "Foundations of Geometry" and Mach's "Science of Mechanics"

I should like to be permitted the liberty of objecting to the statement[2]

"No motion, force or acceleration which exists at the point p can produce rotation of $1-2$ about p as center This must be so, as it is axiomatic in dynamics that, when there is a force or acceleration at the center of mass only of a body, there remains no couple to produce rotation" first, because the word "axiomatic" seems to be used in the Kantian sense of "self-evident," and second, because Dr Northrup's proof (?) in no way depends on whether p has linear or $1-2$ has angular acceleration

Equation 7 of the paper expresses a geometric fact—I am tempted to say "accident" —which text-books raise to the dignity of a theorem R F DEIMEL

[2] *L c*, p 864.

TO THE EDITOR OF SCIENCE Referring to your December 16 issue, if we are to have "A Dynamical Proof of the Pythagorean Theorem," why not let it be a simple one? For instance, if the force F whose rectangular components are X and Y, acts upon a particle of mass m until it has imparted the velocity q whose components in the same plane are u and v, then the work done upon the particle by X is equal to $\frac{1}{2}mu^2$, while the work done by Y is $\frac{1}{2}mv^2$ But the work done by the components is identical with the work $\frac{1}{2}mq^2$ done by their resultant Equating and cancelling the factor $\frac{1}{2}m$,

$$q^2 = u^2 + v^2$$

But the velocity components u and v are the two legs of a right triangle of which q is the hypothenuse, so that here again is our Pythagorean relation MAYO D. HERSEY

QUOTATIONS

THE TENURE OF PROFESSORSHIPS

AMONG the reforms suggested by the "efficiency expert" of the Carnegie Foundation who investigated the administration of some of the principal American universities was the appointment of professors for a brief period, so that they could be dropped without fuss whenever for any reason a change was desired His idea was to get young, vigorous men, work them hard as long as they could stand the strain, and then pension them off in the interest of efficiency Somewhat similar views have of late been expressed by several univer-

sity presidents—who would perhaps consider a president's position as quite different—and the *Popular Science Monthly* in its March number presents both sides of the case, deciding in favor of permanent tenure. President Butler, of Columbia University, in connection with the recent dismissal of a professor, took the ground that a teacher has destroyed his academic usefulness when he offends against common morality, or against "the dictates of common sense." President Van Hise, of the University of Wisconsin, takes the position that "there is no possible excuse for retaining on the staff of a university an inefficient man." And he complains that it is too often assumed that universities exist for the instructional force. "That the main thing is to give that force a comfortable and happy time, an opportunity for a somewhat easy existence as a teacher, leisure for browsing through literature, and long vacations."

Very likely to the employing class, accustomed to deal summarily with employees earning much more than a college professor, it may seem an anomaly to appoint men permanently instead of leaving them subject to a week's warning. Yet as the *Popular Science Monthly* points out, there are precedents, as in the army, the navy and the higher courts, and permanence of office, when introduced, is intended to improve the service, not to demoralize it. "It is attached to honorable offices, where public spirit and self-sacrifice are demanded, and the wages do not measure the performance."

It may be urged, of course, that in the interest of efficiency the wages should be made to measure the performance, that the teaching business should be put on a cold-blooded commercial basis, with no sentimental nonsense. Let every university bid for the best men, and discharge any employee when a more efficient man for the job can be found. The system works after a fashion in the business world, though even there its full rigor is only applied now and then by remorseless employers. The general rule even in business is that a man is retained while he gives reasonable satisfaction, even though it might be possible to fill the post in a more ideal fashion. Perhaps that, too, will come when the efficiency experts have completed their reform of American business system.

How it would work in the academic world is another matter, and opinion may differ as to whether it would produce more efficient or less efficient teachers than are found under the present easy-going old-fashioned ways. The one sure thing is that it would bring in a very different type of man. Of course if the machine is to be "speeded up" and only the young and energetic are to find a place in it, the pecuniary rewards must be made commensurate if the profession is to be made attractive to men of ability. And without doubt the offer of gorgeous salaries would draw in brilliant young men who now see nothing worth while in teaching because they can make more money in business. But that the net result would be a strengthening of the teaching force is by no means so certain. What efficiency experts sometimes forget is that there is a type of ability that can be found and retained better by the offer of a secure and dignified post than by the flourishing of money. The *Popular Science Monthly*, which is by no means sentimental, hits at an important truth when it says:

> But it appears that the general course of social evolution is not toward competition. In the university it would probably be adverse to the finer traits of scholarship and character, most of all when, as under our present system, the competition would be for the favor of presidents and trustees.

No doubt a university tends to accumulate "deadwood," and it is easy to understand the desire a president must often feel to make a clean sweep. Nevertheless it is probable that these disadvantages are more than offset by the republican spirit which prevails in the faculty of a happily governed college or university, the spirit of equality and of disinterested service. It would be a pity to have the seclusion of the university, the citadel of idealism, given up to selfish scrambling for a better "job."—Springfield *Republican*.

THE STATUS OF THE PROFESSOR

THAT the American college president fulfils a function and exercises a degree of power that has no parallel in the institutions of learning of the old world has been asserted so often and, so far as we know, has met with so little contradiction, that it is pleasing to find two leading representatives of the college presidency not so much justifying this peculiarity, but rather denying its existence In the *Popular Science Monthly* for March the editor, in an article under the title "About Dismissing Professors," quotes a comment of President Butler's upon the following remark made in this paper some months ago, in reference to the plans of Reed College, the promising new institution about to be established in Oregon

There is a fine opening for a new institution to show what a college can be wherein the personal domination by the president is abandoned, and in its stead we have a company of gentlemen and scholars working together with the president simply as the efficient center of inspiration and cooperation

"The condition described in the last four lines," says President Butler, "is precisely what is to be found at every American college and university that is worthy of the name, and no evidence to the contrary has ever been produced by anybody"

The other utterance to which we have reference is the address delivered by President Van Hise at the recent meeting of the Association of American Universities at Charlottesville, which appears in SCIENCE for February 17 Doctor Van Hise makes out a very good case for the necessity of the presidential functions, a not inconsiderable part of which case consists in pointing out the extent to which, in many of our colleges and universities, those functions, so far as appointment and promotion are concerned, are exercised only in cooperation with the faculty If anybody was under the impression that the American college president exercised his powers in the spirit of an oriental monarch habitually putting this man up and that man down, as suited his pleasure or whim, certainly the facts stated by Doctor Van Hise must show him that he was in error

The fact remains, however, that in our American colleges the president is not "*simply* the efficient center of inspiration and cooperation," but is in large measure thought of, and thinks of himself, as the master, or the foreman, or the captain, of a body of men working under his direction, and this fact has a potent influence on the whole character and spirit of academic life in America The idea of administration, of coordination, of "harmony," plays a part in most of our colleges and universities altogether disproportionate to its value Nor is the objection to this state of things merely negative There is positive harm of the most serious kind in that submergence of self-assertive personality on the part of the professors which inevitably goes with it It is not an accident that President Van Hise habitually speaks of "the instructional force of the university", he instinctively thinks of the professors not as an assemblage of individuals, each expected primarily to do his own work in his own way, but as a "force" of employees jointly engaged in the production of a certain output Nor is it easy to imagine a man who regards himself as "simply the efficient center of inspiration and cooperation" of the faculty using this language, which appears in an editorial article in the *Educational Review*

Truly the academic animal is a queer beast If he can not have something at which to growl and snarl, he will growl and snarl at nothing at all

Whether or not a bill of particulars could be made out, such as would satisfy a judge and jury, in support of the proposition that the presidents of most American colleges dominate them in the way that is generally asserted, we can not undertake to say Evidences of a less definite nature, but to our mind quite convincing, are sufficiently abundant We do not say that it is personally the fault of the presidents; it may be quite as much the fault of the professors, or the fault of something in the national make-up It may in part be due to the same traits of national character which result in the extraordinary power of the political

boss and in the amazing concentration of financial and industrial control in the hands of a few men But that no need of our university world is keener than the need of an increase in the personal importance, dignity and self-assertion of the professor, we are profoundly convinced And it is encouraging to note that on every hand when the issue arises sentiment is strongly manifested on the right side The dismissal of Professor Ross from Leland Stanford found nowhere stronger condemnation than among men thoroughly out of sympathy with his economic views, but deeply conscious of the importance of professorial independence The report recently made to the Carnegie Foundation by a mechanical engineer was at once recognized everywhere as a *reductio ad absurdum* of the idea that colleges and universities should be conducted on machine-shop principles The attempt to get the maximum of efficiency at every point by the exercise of supervision and control, even when not carried to that ridiculous extreme, is destructive of that vitality upon which the true efficiency of a university depends, and which resides in the inherent personal qualities of its professors It is the permanence of tenure of professors, the undisputed dignity and honor of their position, that have made the great universities of the old world what they are And no substitute for the vitalizing influence of these essential elements can be provided by any amount of supervisory meddling or administrative perfection —New York *Evening Post*

SCIENTIFIC BOOKS

Conduction of Electricity through Gases and Radioactivity By R K McClung Philadelphia, P Blakiston's Son & Co Pp xiv + 245

Among the many books which have appeared upon this subject within the past five years this is the first which attempts to present a definite course of instruction "suitable for the less advanced student or undergraduate" The feature which differentiates it most markedly from other books and which gives it its great importance is the presentation of detailed directions for 125 laboratory experiments The book is in fact built up about these experiments and any student who performs them all can scarcely fail to gain a fundamental grasp of the principles of gaseous conduction and radioactivity

It may perhaps be questioned whether many undergraduates will be found who will have either time or ability to perform satisfactorily all of the experiments outlined—in fact, I confess to a suspicion that perhaps no one person has ever performed all of them, for I should estimate that that would be a task requiring four or five years of continuous work by a well-trained experimenter Nevertheless, the book is a great boon for the student who is just beginning research in this field as well as for the instructor who is directing it, for it collects in compact, accessible form a multitude of practical points which are essential to successful experimenting, but which each individual experimentor has heretofore had to "dig out" for himself or else to obtain from some more experienced person by the laborious process of individual oral instruction

The one danger which will have to be guarded against is that the student by virtue of being crowded too rapidly over the experimental ground covered by practically all of the important researches in this field of the past fifteen years does not develop the habit of very superficial experimenting The book meets an important need and will doubtless receive wide use R A MILLIKAN

RYERSON LABORATORY,
UNIVERSITY OF CHICAGO,

Die Ernahrung der Wassertiere und der Stoffhaushalt der Gewasser Von AUGUST PUTTER Jena, Gustav Fischer. 1909. Pp 168. Price M. 5 0

Dr Putter's researches on the food of aquatic animals have called attention to a source of supply which had been almost or quite disregarded Some of the views expressed in his earlier papers met with more or less criticism because the results obtained by other investigators were not always in accord

with his theories and the present volume is a welcome contribution because Dr Putter gives a more detailed presentation of his views and replies to the more important objections offered by his critics

The first chapters are preparatory to the discussion of the chief topic, i e, how aquatic animals obtain an adequate supply of food They deal with such questions as the intensity of metabolism in the various groups of aquatic animals, the food requirements of these animals, the different types of food of various groups, including both vertebrate and invertebrate forms, and the source of organic substances dissolved in the water The view is presented that the estimation of the food requirement of an animal should be based upon the area of active absorbing and secreting surfaces, more especially the effective respiratory surface, rather than upon the mass, because the oxygen consumed is a good measure of metabolism, and the rate of consumption of this gas shows the intensity of this process Calculated on this basis, the author finds that the food requirement of many aquatic animals has been greatly underestimated hitherto and that the total demand in a body of water is frequently greater than the supply of organized food which is produced by it One instance is cited in which the demand for food by the zooplanktonts of a body of water exceeded the supply of organized food for nine months out of a period of thirteen, and in another instance demand exceeded supply for each of thirteen months Naturally, this excess of demand over supply raises the question as to how this deficit is made good and the author's answer to this query is his important contribution to the subject under discussion

Dr Pütter maintains that aquatic animals have recourse to the organic substances which are always found in solution in natural waters, and in this way the deficiency is supplied He asserts, in fact, that these dissolved organic substances which are generally present in amounts varying from ten milligrams to twenty milligrams per liter of water are not only drawn upon in emergencies, but that they are the chief source of the food of some forms

With respect to the ability of aquatic animals to make use of dissolved food an experiment by Knorrich is cited in which *Daphnes* survived for a period of fourteen days on a diet consisting solely of dissolved food The author himself found that goldfish lived for a period of forty-one days in tap water which contained no organized food and the oxygen consumed substantially accounted for the loss in weight, but when organic substances were dissolved in the tap water, the goldfish survived for seventy-eight days, nearly twice as long, and the oxygen consumed greatly exceeded the amount that would account for the loss in weight The conclusion drawn from this experiment is that these goldfish were able to make use of the dissolved food, because they lived so much longer when supplied with this kind of food than when given neither dissolved nor solid food, and because of the extra quantity of oxygen consumed

Solid food is not regarded as a thing which may be dispensed with entirely, but dissolved food may play a more or less important rôle, even to the point of being the chief source of food for some organisms, such as sponges, which frequently appear to receive very little in the way of organized food

Dr. Putter's conclusions are not always convincing and there is a paucity of evidence in some instances which serves to show how recently this field has been invaded by investigators, but the views expressed are suggestive and will doubtless stimulate investigations in this field of research and eventually result in giving us a much better knowledge of the nutrition of aquatic animals

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE
SECTION E

THE regular annual meeting of Section E of the American Association for the Advancement of Science was held in Pillsbury Hall, University of Minnesota, December 27, 28 and 29 A program of papers was read both morning and afternoon each day Due to the unavoidable absence

of Mr. Brock, the vice-presidential address on "Northern Canada" was not read on Wednesday afternoon, but read by title only.

The Weathering and Enrichment of Pyritic Gold Ores: W. H. EMMONS.

Any theory of leaching or enrichment at depth of auriferous deposits involves the solution, transportation and precipitation of gold in cold and moderately dilute solutions. The analysis of underground waters shows that sulphuric acid and sodium chloride are present in practically all waters from pyritic gold mines. Gold is dissolved by nascent chlorine, which in acid solutions is set free by nitric, manganitic, ferric or cupric compounds. Since nitrates are seldom shown in the analyses, they are believed to be of little or no importance in this connection; ferric and cupric compounds release nascent chlorine only in hot or in concentrated solutions. As shown by Brokaw's experiments appreciable gold is dissolved in fourteen days in cold solutions containing but 1,418 parts per million of chlorine, when manganese is present. In a similar solution without manganese no gold is dissolved. As shown by McCoughy a very small amount of ferrous salt will precipitate gold dissolved in chlorine solution. Consequently the auriferous solution could not travel far through deposits where pyrite is oxidizing to ferrous sulphate. But manganitic compounds such as pyrolusite very quickly oxidize ferrous salt to ferric salt. Thus manganitic compounds not only release the nascent chlorine which dissolves gold but they also inhibit the precipitation of gold by ferrous salt, thus permitting the gold to travel farther in solution.

But these laws apply only to acid solutions. At greater depths where acid is used up to form neutral or basic salts by reactions with the wall rock, the system breaks down and gold together with manganese oxide is precipitated. Indicating these reactions certain manganiferous gold deposits are found in depth to consist of pyritic gold ore cut by fractures which are filled with rich veinlets of auriferous powdery manganese oxide (probably manganite, in the main).

It follows from these premises that manganiferous gold deposits are less likely to yield gold placers than non-manganiferous deposits; that outcrops of manganiferous lodes are more likely to be leached of gold near the surface, that non-manganiferous lodes are less likely to contain secondary gold bonanzas. It is believed that these relations are indicated by the pyritic gold deposits of the United States.

The Genesis of Certain Greensands of Minnesota: N. H. WINCHELL.

The greensands discussed were (*a*) that which occurs in the valley of the Blue Earth River, discovered in 1700 by Le Sueur and mined by him in the belief that it was an ore of copper, and (*b*) that which occurs on the Mesabi iron range, called glauconite and greenalite, and regarded by some as the source of the iron ore of that range and of other Lake Superior iron ranges.

The former was shown to be so closely associated with the residual products, such as kaolin, that it must be considered to result from the decay of the Upper Cambrian strata with which it is found. The chemical and physical characters were given, samples were shown, and finally, photographs of the bluffs showing the deep disintegration of the strata along the Omaha Railroad. Kidney iron ore (with the shape of limestone pebbles, which have been a standing puzzle to Minnesota geologists) was another product of this same disintegration, which was in some way dependent on the presence of the Cretaceous ocean, which covered the locality.

The greensand of the iron ore ranges of Minnesota has been reinvestigated by means of thin sections of a drill core furnished by Mr. E. J. Longyear, of Hibbing. This core was representative of a drill that went through the Mesabi rocks, to a depth of 2,049 feet. One hundred and six thin sections were examined. Throughout the core, beginning at the top of the black slate and continuing to near the horizon of the iron ore, the rock is characterized by the predominance of an isotropic substance in grains of all shapes, evidently sedimentary, though seldom in distinctly detrital or rounded forms. The supply of material was so rapid that there was not enough friction to round the grains thoroughly. Mingled with these grains are angular grains of quartz and other minerals. The isotropic grains resembling glass, are seen to contain bubbles and globular incipient minerals. They are sometimes slightly greenish, and sometimes brownish, but have a high index of refraction. They are sometimes partly and even wholly opaque, and black, and when opaque they are variable in form. These obvious primary microscopic characters indicate that this isotrope is of volcanic glass, and the secondary microscopic characters agree with

that conclusion Quartz, actinolite, calcite and iron ores appear as alteration proceeds, and their relations have been noted The green mineral first appears at a depth of 1,508 feet, where it is only partially developed and hardly to be distinguished from the isotropic glass It occurs in various *forms* and first attracted attention as it took the rounded form of the original glass pellets, wholly free from other secondary minerals The detailed relations were examined Geodic structure often appeared

Inasmuch as these several secondary minerals often lie in a matrix of greenalite, it has been assumed that they have been developed from the greenalite by chemical separation But an identical fact is seen in the relations of secondary quartz Magnetite, actinolite, and even greenalite and calcite are similarly surrounded by quartz. From analogy, one might assume that these minerals were generated from quartz On such an assumption any one of the minerals could be proven to be derived from any of the others

These considerations put a veto on the idea that the iron ore is derived from the greenalite It is a secondary product coordinate and connate with the quartz and with the iron ore

An Example of Limonite Deposition. OLIVER BOWLES

A small occurrence of limonite at Sturgeon Lake, in the Thunder Bay District of Ontario, is described Surface waters have dissolved pyrite from a pyritic quartz vein which is exposed on a hillside, and the dissolved iron is deposited in the form of a limonitic cement amongst the pebbles of the talus slope

The points to which attention is specially directed are (1) evidence of total solution of pyrite by rain water assisted only by dissolved gases, (2) the large extent of the deposit when compared to its limited source of supply; (3) the presence of ferrous sulphate as an intermediate stage in the process of alteration The unstable nature of ferrous sulphate when considered in connection with the close proximity of the pyrite and limonite would lead one to expect that limonite deposits of pyritic origin, in regions free from carbonate reaction, would be found close to the source of supply

The Geology of the Cuyuna Iron Ore District of Minnesota CARL ZAPFFE.

Cuyuna District is located in central Minnesota and is the youngest iron ore district in the Lake Superior region No rock outcrops point directly to its location, but its existence was conjectured from the geological structure of the Lake Superior region as a whole and that of the different iron ore districts embraced therein Numerous well-defined belts of magnetic attraction enable systematic and productive explorations with diamond drills, and the geology of the district has been determined solely from carefully collected data of about 1,900 drill holes The geology of the district is interpreted to be that of a closely folded heterogeneous slate formation of Upper Huronian age and containing in its lower horizon interbedded sedimentary lenses of iron bearing formation which, upon being exposed by folding and erosion, have frequently altered through descending meteoric waters into low grade iron ores at the erosion surface Basic post Huronian igneous rocks seem to be exclusive within the ore bearing area and predominate over the acid phase in the outlying areas

The Relation of Texture to the Composition of Coal FRANK F GROUT

Proximate and ultimate analyses are reported of seven samples from a coal mine at Marshall, Colorado The samples represent different textures from a single seam, and in the report they are distinguished by the following names (1) average, (2) glance coal, (3) splint coal, (4) mineral charcoal or "mother coal," (5) cannel-like coal, (6) resin? (7) slate, (8) bone coal

It is seen that the average of the seam is sub bituminous, but that by any of the standard methods of chemical classification the small samples vary from lignite to semi-bituminous coal. The analyses have considerable importance in discussions of the origin of coal, and further, may explain some of the variation in samples from a single seam It is well known that such constituents as the resin and charcoal occur quite erratically in various parts of the mines

The Geology of Harding County, South Dakota: ELLWOOD C PERISHO.

This area is located in the northwest corner of South Dakota Topographically the chief feature is a plain about 3,000 feet in elevation with several buttes and a few valleys The buttes are about 500 feet high; good examples are Cave Hills, Short Pine Hills and Slim Buttes, while the chief valleys are the Little Missouri, Grand and Moreau. The geological formations are the Fort Pierre, Cretaceous to Loup Fork and Mio

cene Unconformities occur between the Fort Union and White River and between the White River and Loup Fork, while folds and faults occur locally in the Pre Loup Fork beds of Short Pine Hills, etc There are few fossil plants and animals Coal (lignite) of lower Fort Union age occurs in seams a few inches to ten feet thick

The buttes are attributed to either (1) a chert layer of the White River, (2) a massive Fort Union sandstone, (3) local thick coarse beds of Loup Fork, (4) combinations of the above

Soil has been extensively removed and caves worn in the cliffs by the work of wind At Slim Buttes and Short Pine Hills extensive slumping has developed Some terraces in the Little Missouri Valley may be due to the post Pliocene climatic changes

Northern Canada (address of the retiring vice president) R W BROCK Read by title only

Geology of the Olympic Peninsula, Washington · A B REAGAN

In the Olympic Peninsula the following formations are exposed (1) Old Cretaceous (Point of Arches group), (2) Cretaceous and possibly older (Point Granville, Pacific coast in general, and central high area), (3) Eocene (Volcanics near Port Crescent), (4) Oligocene Miocene (Fresh Water Bay and east of Gettysburg flank of the Point of Arches Group), (5) Pliocene (Hoko formation on the Strait, Raft and Quinault formations toward Point Granville, and Quillayute formation in the interior to the northeast of La Push on the Pacific), and (6) Pleistocene (covering all the region but the upper stretches of the eastern tributaries of the Quillayute River) In all between 20,000 and 30,000 feet of rocks are exposed

The rocks of (4) contain many fossils very similar to the Tertiary near Astoria, Ore They are also coal bearing, the Clallam Bay Mine producing 200 tons or more per month Coal is also exposed in the Quillayute Bogachiel country and on the Pacific coast near Cape Johnson, and also near the Point of Arches Oil springs occur at Hoh Head, on the Pacific side of the peninsula

The Geologic Map of North Dakota A G LEONARD

The geologic formations represented on the map are the Benton, Niobrara, Pierre, Fox Hills, Lance (*Ceratops* beds)?, Fort Union and White River The Benton and Niobrara occur in the northeastern corner of the state, in the Pembina Mountains The black to bluish gray Pierre shale covers most of the eastern half outside the Red River Valley, and also outcrops in the Missouri River Valley for twenty miles above the South Dakota line, and in a small area in northwestern Bowman County The Fox Hills sandstone occurs in the latter locality and on the Missouri River as far north as old Fort Rice The Lance beds cover a large area in south central North Dakota, and a smaller area in the southwestern corner of the state The Fort Union occupies much of the western half of the state, and in it most of the lignite beds are formed The White River beds form several small areas in Billings County

The character of the various formations is discussed

The General Structure of the Florence Iron District W O HOTCHKISS

The Florence Iron District is the extension into Wisconsin of the Menominee district of Michigan The Quinnesec schists south of both districts have been considered to be the basement on which the iron bearing series was deposited and therefore the possibility of developing new iron districts to the south deemed very slight Work of the past field season has shown that these schists overlie the iron bearing series The general structure of the Florence district is monoclinal from a broad point of view, with local folding in the slate series in which the iron formations are interbedded

The iron bearing series has a southward dip and disappears under the schists This makes it more probable that the series may reappear beneath the glacial drift to the southward and makes careful work in the drift covered pre cambrian area to the south of great economic importance

The Geothermal Gradient ALEXANDER N WINCHELL

It is generally agreed that the earth is a cooling body Calculations of the thermal gradient within the earth, based on the laws of a cooling body, have shown that the gradient thus derived does not deviate from a straight line to any important amount within a depth of fifteen or twenty miles

Therefore, it has been assumed that temperatures approximating fusion conditions would be found at about twenty miles depth, but such computations ignore the effects of radioactivity on the geothermal gradient. Therefore the subject needs reexamination in light of new data.

A study of the subject leads to the conclusion that radioactivity supplies not less than one sixth nor more than one half of the annual heat loss of the earth. It appears, further, that this source of supply of heat must be largely concentrated near the surface of the earth. Therefore, the actual temperature gradient within the earth can not be approximately a straight line, as derived from the laws of cooling, but must curve constantly and at a rate which depends upon the amount of heat produced within the earth by radioactivity at various depths. After making due allowance for the effects of radioactivity and cooling upon the geothermal gradient it appears that temperatures approximating fusion conditions are to be expected at a depth of about thirty miles instead of twenty miles. Further, it appears that if radioactivity supplies much more than about one quarter of the annual heat loss of the earth the nebular hypothesis as ordinarily understood must be incorrect.

Finally (as pointed out by Becker), by making proper allowance for the effect of radioactivity, Kelvin's estimate of the age of the earth is brought into harmony with the best estimates derived from other sources, instead of standing as heretofore, as a perpetual challenge to the accuracy of other estimates.

Terrestrial Deposits of Owen's Valley, California. ARTHUR C. TROWBRIDGE.

Alluvial deposits occur as fans and piedmont alluvial plains on either side of Owen's Valley, Cal. On the Sierra side the deposits are fluvioglacial. At the foot of the Inyo Mountains there are deposits of two ages. The materials range in size up to bowlders thirty feet in diameter. They are sorted roughly into lenses and pockets. The fans are now being dissected. The cause of deposition is decrease in velocity and volume of streams from the mountains.

Huge bowlders are transported in the following manner. The stream moves fine material from in front of the bowlder and piles other material behind it. As the bowlder is undermined it falls over into the depression. This process is repeated time and again, resulting in periodic motion for the bowlder.

Dissection has followed great fluvio glacial deposits on the surface of the fans, these deposits bearing relations to present conditions similar to those between a valley train and normal stream erosion.

Criteria are presented for the distinction of such deposits from still water deposits.

Note on a Method in Teaching Optical Mineralogy. F. W. MCNAIR. (To be published in *Am. Jour. Science.*)

In the effort to condense optical mineralogy, the form of the wave shell and deductions therefrom have been rested as directly as possible upon the so called reciprocal ellipsoid of McCullough. If one may judge by the text books, the ellipsoid, whether that of Fresnel or this of McCullough, is used in the non mathematical presentations of the subject to obtain the wave shell or its three principal sections, and is then immediately abandoned. The device, which occurred to me some years since and which I have found useful in obtaining results with my students, is to carry the use of the ellipsoid into a considerable number of the applications of the theory to the properties of crystals. Perhaps the most conspicuous example of its usefulness lies in its application to the distinction between positive and negative crystals in convergent polarized light. Details can not be abstracted.

Its justification rests in the readiness with which a student who once comprehends the meaning of the ellipsoid becomes independent in his application of the test of the quartz wedge, applying the wedge in either position and reasoning out his results with an assurance of correctness.

Indications of a Huronian Continental Angle. H. B. AYERS.

A belt of Huronian beds will probably be found parallel to the Rocky Mountains through the Dakotas, Alberta and northwestward, forming a continental angle with the Minnesota belt probably in the vicinity of the Black Hills. A few outcrops of quartzite and slates and some topographic and drift data supply the foundation for the conjecture.

The Dam Lake Quartzite. H. B. AYERS.

The quartzite of Dam Lake (Aitkin County, Minn.) has been explored by drilling through both contacts with adjoining rock and the results prove it to be the equivalent of the Pokegama quartzite, and here overlying the Keewatin formation.

Evidences of Pleistocene Crustal Movements in the Mississippi Valley: J. E. TODD. Read by abstract.

Recent studies show that the glacial deposits of Kansas indicate: (1) A marked easterly trend. This appears from the direction of striæ, character of bowlders, etc. The ice came from the Minnesota valley, not from the Dakota. (2) The edge of the ice reached, in Pottawattamie County, Kansas, an altitude of 1,500 feet A. T. Taking a common point in northern Kossuth County, Iowa, and assuming a uniform average slope, it is shown that with the surface at present altitudes, if the ice reached Blaine, Kan., in the Kansan epoch, it should have reached scores of miles farther east in northeastern Iowa, and seventy or eighty miles further southeast in central Illinois, than any trace has yet been found. From this it is argued that the surface at that time was higher in the latter localities and lower in Kansas.

Corroborating facts are found: (1) in the trough of the Mississippi being 100 to 200 feet deeper than is now necessary to fit the present levels of drainage, while (2) in Kansas the levels of pre-glacial drainage and Kansan drainage were 80 to 100 feet higher than at present. (3) The stronger easterly trend in eastern Iowa of the ice of the Iowan epoch, as compared with that of the Kansan agrees with the conclusion that the change of levels took place between the two epochs, presumably in response to the presence and weight of the ice.

Fault Scarps of the Basin Ranges: CHAS. R. KEYES. Read by abstract.

In the instance of the Basin-Range type of mountain structure normal faulting on a prodigious scale was long regarded as the principal factor. Its mountain block was considered as upraised. The face of the hard mountain rock rising abruptly out of the less resistant valley deposits was believed to represent a true fault scarp. This hypothesis is not exclusive; nor is it very satisfactory.

A main objection to the theory is the fact that the evidences of recent displacement are seldom ever disclosed at or even near the so-called fault-scarps. Whenever the line of major faulting is discovered it is miles away from the mountain foot—out on the intermont plain.

On the theory of general denudation of arid regions chiefly through means of eolic rather than aqueous agencies the belt of maximum deflation is at the foot of the desert ranges—where the mountain meets the plain. Within the limits of this narrow belt the topographic result is a tendency towards a steep, plain-like slope. This piedmont belt chances also to be the horizon where torrential water action is most pronounced, cutting deep canyons in the mountain and spreading out detrital fans on the plains. In the struggle between water and wind for corrosive supremacy the results in the mountain area are a succession of sharp ridges trending at right angles to the range axis, sharply truncated at their lower end by deflative action. The faceted mountain foot thus produced resembles closely the ideal effects of a fault-bounded upraised mountain block the dissection of which is well advanced.

Modified Drift in Minnesota: WARREN UPHAM.

In respect to their origin and mode of deposition the drift formations of the Ice Age comprise two classes: (1) glacial drift, in the various phases of the till and morainic deposits, produced directly by the agency of ice-sheets, without modification by water; (2) modified drift, derived from erosion and transportation by land ice, but also to some extent transported and deposited by water, being thus waterworn, assorted and more or less stratified.

This second class of the drift deposits, described in its development in Minnesota, includes the valley drift gravel, sand and clay, and also frequent tracts of sand and gravel plains outside the present courses of drainage, but occupying areas where considerable streams of water, well laden with sediments, were discharged from the melting and retreating ice fields. Relatively small parts of the modified drift are amassed here as kames and eskers, which are respectively knolls and long ridges of gravel and sand formed by the brooks and rivers of the glacial melting, the heaped and ridged form of these deposits being due to accumulation at the mouths and in the ice-walled channels of the streams.

The ratio or proportion of the modified drift and glacial drift in Minnesota is estimated as one to three or four. This somewhat large proportion modified and deposited by water, is regarded by the author as an evidence that much of the drift was contained in the lower part of the ice sheet, and that it was finally exposed on the surface of the waning ice fields to the action of streams formed by the melting and by attendant rains.

Fluctuations of the Keewatin and Labradorean Ice Currents in the Vicinity of Minneapolis and St. Paul: WARREN UPHAM.

The currents of glaciation in western and south-

western Minnesota moved to the south and southeast, bringing gray till, with plentiful limestone bowlders, cobbles and finer drift This area was a part of the Keewatin division of the continental ice sheet, with outflow southward from Manitoba, Saskatchewan and Keewatin In northeastern Minnesota the glacial currents belonging to the outer part of the broad Labradorean ice field, moved to the southwest and south, bringing reddish till, colored by the red sandstones and shales of Lake Superior The red drift is destitute of limestone bowlders and detritus, because that part of this state and the adjoining region northeastward have no limestone formations The Keewatin and Labradorean currents were confluent, or they met and opposed each other on a belt that extends from St Paul and Minneapolis northward and northwestward through Minnesota to the vicinity of Winnipeg

Gray drift forming the surface and overlying the red drift on a large tract from Lake Minnetonka east and northeast to Rush City, Minn, and to the contiguous border of Wisconsin, shows that after the edge of the Labradorean ice field had occupied that area its drift was covered by an advance of the edge of the Keewatin ice field

Numerous sections in St Paul, observed in the distance of about three miles from the new capitol to Lake Como, show that stratified drift gravel and sand, mostly from the northwest, with abundant limestone, are covered by a thin surface deposit of till from the northeast, having no limestone The latest fluctuation of the waning ice sheet there is thus known to have been a readvance of the Labradorean margin, spreading a thin mantle of its englacial till

The Glacial Lake of the Fox River Valley and Green Bay and its Outlet S WEIDMAN

An introductory statement was made of the succession of glacial lakes in the basins of the Great Lakes, and the generally accepted theory of their origin by ice dams on the retreat of the latest (Wisconsin) ice sheet Professor Upham pointed out the probable existence of such a lake in the Fox Valley, suggesting the name Lake Jean Nicollett, but not describing the shore lines or outlet. Recently discovered shore lines in the valley and about Green Bay occur at about 20, 40, 70, 95, 150, 220 and 250 feet above the present level of Green Bay. The higher shore lines are at 800 and 830 feet above sea level, developed on the outlet to the Mississippi River by way of the Wisconsin, the outlet being below the mouth of the Baraboo River, south of Portage The lower shorelines marked stages in the lake with outlets probably first through Lake Chicago and later through to the Atlantic The shore lines appear to be horizontal throughout

The outlet for altitudes of 800 and 830 feet developed across what seems to have been the divide between the Fox and lower Wisconsin River systems, this divide being between the mouth of Baraboo River and Merrimac The Wisconsin River above Portage was formerly a part of the Fox River system, and through the development of the lake outlet was captured by the lower Wisconsin, a tributary of the Mississippi During flood the Wisconsin now overflows to the Fox across the low flats in the vicinity of the canal and old Indian portage at Portage, the overflow following approximately the former course

Characteristics of the Glacial Drift Sheets in Minnesota FREDERICK W SARDESON

A brief historical review of recognized drift sheets in Minnesota, the Old Drift, the Young Drift and recognizable divisions of these, were given, followed by a description of their general characters Local variations in the character of the several sheets were considered with discussion of means employed to identify them under various conditions The progress of new investigations by Leverett and others in Minnesota was also represented

The Pleistocene of a Portion of the Missouri Valley B SHIMEK

A discussion of the distribution and extent of the Nebraskan drift, the Aftonian interglacial silt, sand and gravel, and the Loveland joint clay, as revealed by recent field studies Evidence that the drift of the extreme northwestern part of Iowa, and adjacent territory is Kansan, and that the Wisconsin is absent from that section. The wide distribution of at least two loesses is noted.

The Æolian Origin of the Loess B SHIMEK.

The evidence furnished by distribution, composition and fossils is briefly reviewed Elimination of fossils formerly improperly included in the loess series Additional evidence furnished by observations on the drifting of sands, dust and snow, on plant distribution and distribution of the loess along streams. A brief summary of objections to all other theories of origin of loess

Chains of Lakes in Martin County, Minn., as Evidence of Extensive Recession and Readvance of the Ice sheet WARREN UPHAM Read by abstract only

Three series of lakes extend across Martin County, one of the central counties of the most southern tier in Minnesota Till forms the moderately undulating and almost level country inclosing these lakes, which are usually joined by a stream In several places, however, a watershed passes across a lake chain, and such higher divides between closely adjoining lakes of the chain likewise consist of till, retaining their contour as molded by the ice sheet, without effects of water in deposition or in erosion These very remarkable chains of lakes seem explainable only by regarding them as proofs of a fully developed interglacial system of drainage running there from north to south, which became afterwards ice enveloped in the Iowan and Wisconsin stages of the glacial period

Near Rush City in Chisago County, about fifty miles north of St Paul, and at Barnesville, Clay County, in the southern part of the Red River Valley, fossiliferous beds and associated modified drift were overspread by till of a later glacial readvance Probably this renewal of glaciation covered nearly all the south half of Minnesota, extending over Martin County with partial filling of its interglacial river courses, and continuing to the most southern limits of the Wisconsin drift sheet west of the Mississippi River, near Des Moines, Iowa, distant from Barnesville about 400 miles to the south southeast

The Glacier National Park M J ELROD

About 125 colored lantern slides, mostly from the author's negatives, showing the condition, surroundings and effects of the several glaciers of the park.

Observations on Changes of Level on the Atlantic Coast Line from Cape Cod to Cape Race (Newfoundland) G C CURTIS Read by abstract only

A series of observations have been completed on the coast and outlying islands between Cape Cod and Cape Race The general character is that of old mountains partly submerged and subsequently elevated Local differential movements appear to be a characteristic throughout the area Sections of coast plain alternate with fiorded indents Since glaciation there has been a very general elevation of between twenty and forty feet, sometimes more and sometimes practically none. In general the Nova Scotia coast appears to have remained longer at the present level than that of Maine. The character of local coast features has been modified by glacial drift.

The Contribution which the Naturalistic Model is bringing to Earth Science G C CURTIS Read by abstract only

Up to the last decade, representation of the earth's surface has been generally held an empirical subject Modern science has permitted its development along natural principles To day it may be considered an exact art based on the laws of nature We are just beginning this work, which has probably the power to bring a more general interest and better appreciation for the land on which we live than has before been possible The distinction between the diagrammatic relief map and the true model is now being generally used, under the auspices of Alexander Agassiz, a naturalistic model of the topographic type has been made of the coral island Bora Bora, and installed in the Museum of Comparative Zoology (Harvard) The naturalistic model is the most perfect representation that can be made of the earth's surface, giving a truer conception of the forms of geography than can possibly be obtained otherwise The results based on following natural principles are so far superior to those of the mechanical methods and the work has so different an appearance that it seems like a different subject

Original Geographic Work ROBT BELL Read by title only

Reciprocal Intercision by Parallel Streams G H CHADWICK Read by abstract

Two parallel streams cut through the beaches of former Lake Iroquois, in the town of Lorraine, Jefferson County, N Y When close to the lake, these streams meandered somewhat, and one captured a tributary of the other Since the lowering of the lake level, both streams have cut gorges in the soft shale In much more recent times, the tributary mentioned has, in one of its meanders, up stream from the first point mentioned, cut through the wall of the larger canyon and given itself up, it can hardly be called a capture by the larger stream.

Artesian Water of South Dakota: ELLWOOD C PERISHO Read by title only

The Material Conditions of a Municipal Water Supply. C. W HALL

A study has been made of the water from all the local geological formations and from the various surface sources Several points are worthy

of special notice (1) A general tendency toward an increase in hardness with depth, or with age of the rocks from which the water is drawn (2) A tendency for the hardness of the water to decrease, if drawn extensively and continuously from a certain sandstone for several years (3) The clear evidence furnished by the chlorine determinations, of pollution of surface waters and shallow wells in the cities. In south Minneapolis—the older, more densely settled part of town—shallow well waters contain 44 parts per million of chlorine, while in other, less settled parts, 4 parts per million is the maximum A few analyses follow

	1	2	3	4	5	6	7	8
Total solids	202.1	247.3	303.9	288.5	346.9	220.0	327.6	280.0
Silica	16.6	18.2	11.6	12.3	16.8	5.0	13.1	6.7
Iron oxide, etc	.7	1.4	1.9	1.3	6.7	.6	3.1	2.2
Calcium	40.3	52.2	60.1	63.1	95.1	57.5	75.8	51.6
Magnesium	12.7	16.8	25.1	26.1	24.6	22.0	29.1	20.1
Sodium and potassium	4.9	14.1	7.1	9.4	11.3	6.8	6.8	10.2
Carbonate radicle	trace	4.2	.8	2.6				
Bicarbonate radicle	201.3	207.8	298.2	338.6	414.5	278.0	377.5	252.0
Sulphate radicle	9.5	10.6	14.0	8.4	19.8	4.0	15.5	2.7
Chlorine	2.2	8.8	5.3	5.6	6.9	4.6	2.4	5.3

It is noteworthy that samples number 6 and 8 from St Paul have lower mineral content than samples number 5 and 7 from Minneapolis, though from the same formations The amount of water taken from these formations in St Paul is much greater than in Minneapolis

1 Lake and river waters
2 Waters from wells in glacial drift
3 Saint Peter sandstone waters
4 New Richmond sandstone waters
5 Jordan sandstone waters of Minneapolis
6 Jordan sandstone waters of St Paul
7 Dresbach sandstone waters of Minneapolis
8 Dresbach sandstone waters of St Paul

Acting Secretary

SOCIETIES AND ACADEMIES

THE AMERICAN MATHEMATICAL SOCIETY

THE one hundred and fifty second meeting of the society was held at Columbia University on Saturday, February 25 Thirty eight members attended the two sessions President Henry B Fine occupied the chair The council announced the election of the following persons to membership in the society Dr Elizabeth R Bennett, University of Nebraska, Mr Daniel Buchanan, University of Chicago, Dr H. B. Curtis, Columbia University; Mr L L Dines, University of Chicago, Professor C R MacInnes, Princeton University, Professor Eva S Magiott, Ohio Northern University, Mr R E Root, University of Chicago, Professor Sarah E Smith, Mount Holyoke College Six applications for membership were received

The following papers were read at this meeting

E J Miles "Some properties of space curves minimizing a definite integral with discontinuous integrand"

N J Lennes "A necessary and sufficient condition for the uniform convergence of a certain class of infinite series"

N J Lennes "Duality in projective geometry"

G A Miller "The number of the abelian subgroups in the possible groups of order 2^m"

C N Moore "On the uniform convergence of the developments in Bessel functions"

G D Birkhoff "A direct method for the summation of developments in Lamé's functions and of allied developments"

Edward Kasner "Equitangentials in space"

Edward Kasner "Conformal and equilong invariants of horn angles"

J A Eiesland "On a contact transformation in physics"

D C Gillespie "Definite integrals containing a parameter"

Joseph Bowden "The Russian peasant method of multiplication"

N J Lennes "A direct proof of the theorem that the number of terms in the expansion of an infinite determinant is of the same potency as the continuum"

Harris Hancock "On algebraic equations that are connected with the cyclotomic equations and the realms of rationality which they determine"

W B Fite "Irreducible homogeneous linear groups of order p^m and of degree p or p^2"

The next meeting of the society will be held at the University of Chicago on Friday and Saturday, April 28–29 On this occasion Professor Maxime Bôcher will deliver his presidential address, the subject of which will be "Charles Sturm's Published and Unpublished Work on Differential and Algebraic Equations" Except for the summer meetings, this will be the first convention of the whole society since 1896. A large attendance is expected from both east and west

The San Francisco Section of the society will meet at Stanford University on Saturday, April 8.

F. N COLE,
Secretary

THE AMERICAN PHILOSOPHICAL SOCIETY

The Investigation of Explosives at the Pittsburgh Testing Station Professor CHARLES E MUNROE, Washington, D C

The many and increasing number of accidents giving rise to serious casualties that have attended the mining of coal has in recent years led thoughtful men to inquire into the causes of such accidents with a view to their prevention Among other causes, it was found that the improper use of explosives, or the use of improper explosives had often operated to produce these accidents, and it appeared evident that here was a cause that ought, by study of materials and methods, to be remedied This study was begun some years ago, but it was much advanced when, following a series of disasters in the fall of 1907, by which 623 men were killed, Congress appropriated money for the investigation A testing station was opened at Pittsburgh in the following year, where the explosives could be exploded, under known conditions, in the presence of sensitive fire damp and of coal dust laden air A standard was fixed upon which the explosive must satisfy An explosive which passes the test is styled a "permissible" explosive and its name is published The list about to be published by the Bureau of Mines will contain the names of 69 permissible explosives made by sixteen different American manufacturers These explosives are sometimes styled "short flame" or "safety" explosives, but the term "safety" is improper. According to a canvass by the Bureau of Mines, 8,942,857 pounds of short-flame explosives were made in 1909 Professor Munroe, with the aid of lantern slides, described the apparatus employed and its method of use

THE BOTANICAL SOCIETY OF WASHINGTON

THE 70th regular meeting of the society was held at the Cosmos Club, Tuesday, February 7, 1911, at 8 o'clock P M In the absence of both president and vice president Dr W H. Evans was chosen chairman pro tem Thirty one members were present Dr C O Appleman, E G Boerner, G N Lamb, W J Morse, C A Reed, Wm Shear, C B Smith, A V Steubenrauch and Dr. W. Van Fleet were admitted to membership

The following papers were read

The Effect of Temperature on the Respiration of Fruits H C GORE

The rates of respiration were given of many fruits at different temperatures It was found that the forty different fruits studied obeyed approximately the same law in regard to the effect of temperature The rate of respiration increased two to three times for each 10° C rise, following van't Hoff's rule for increase in rate of chemical reactions with temperature The respiratory activity of the different fruits varied greatly and no correlation appeared between it and composition or size In general, fruits which grow and mature rapidly and soon become over ripe, respired rapidly, while fruits having a long growing season and maturing slowly were much less active

Collecting Grasses in Mexico A S HITCHCOCK

Mr Hitchcock described his recent trip to Mexico for the purpose of collecting and studying the grasses of that region He gave considerable attention in his paper, to the physiographic and climatic conditions and the relation of these conditions to the flora Tables and maps were submitted showing the topography of the country, and the monthly rainfall and temperature of several representative stations The speaker described the floral regions, the distribution of the grasses as affected by rainfall and altitude, and reviewed briefly the agricultural and range conditions, including the forage crops The paper was illustrated with about fifty lantern slides from photographs taken by himself and his son, Frank H Hitchcock, who accompanied him as assistant

The forty localities visited by Mr. Hitchcock included many type localities, which led to the rediscovery of certain little known or doubtful species of grasses described by earlier writers, among which species may be mentioned *Bouteloua repens* HBK, *Panicum decolorans* HBK, *P buchingeri* Fourn, *P. cordovense* Fourn and *P ischnanthoides* Fourn It is highly probable that Mr Hitchcock collected specimens from the same group of plants from which the types of the last two species were obtained On the other hand, species previously supposed to be restricted in range were found to be widely distributed *Panicum arizonicum* Scribn & Merr, known in Mexico only from the northwestern states, was collected as far south as the state of Oaxaca These facts emphasize the point that, when possible, the specialist should make his own collections

The Rediscovery of the Xochinacaztli of the Aztecs, with Notes on Mexican Anonaceæ. W. E. SAFFORD.

Before the conquest of Mexico the Aztecs used certain spices and aromatic plants in confectioning their celebrated chocolate The mostly highly prized by the ancient Mexicans was the flower called *teonacaztli*, or *xochinacaztli* ("sacred-ear" or "ear flower") Up to the present day the identity of this plant has remained a mystery The writer has finally succeeded in tracing it to *Cymbopetalum penduliflorum*, belonging to the Anonaceæ

Cymbopetalum penduliflorum (Dunal) Baillon was called *xochinacaztli* (ear flower) on account of the resemblance of its three inner petals to the human ear It occurs in the mountains of Guatemala and southern Mexico

Sapranthus fœtidus (Rose) Safford the fœtid carrion flower, is very closely allied to the palanco (*Sapranthus nicaraguensis*) of Central America. Another species, with flowers having an equally disgusting odor, but with broader petals and an orbicular bract on the peduncle, proves to be identical with the plant described by Dunal as *Unona violaceus*, and must therefore take the name *Sapranthus violaceus* (Dunal) Safford Specimens of it were collected by Dr J N Rose at Rosario, Sinaloa, in 1897 (No 1842)

Among the well known anonas are the sugar apple, *Anona squamosa*, usually called anona blanca in Mexico, *A reticulata*, the bullock's-heart, or anona colorado, *A cherimolia*, the Peruvian chirimoya, introduced at a very early date into Mexico, and the pleasantly acidulous fruited sour-sop, *A muricata*, usually known as Guanábana in tropical America

Anona purpurea DC, called soncollo, or sincuya, is a species often confused with *A muricata*, which it resembles in having large flowers with leathery petals and fruit covered with projecting points, but its flowers are sessile and its fruit is not edible, while its leaves differ from those of *A muricata* in being much broader and larger

Anona longiflora, usually called chirimoya, is very closely allied to *A cherimolia*. Its flowers, however, are much larger and its leaves, covered with velvety pubescence beneath, are broader and more obtuse It was first described by Sereno Watson from specimens collected by Dr Edward Palmer near Guadalajara in 1886

Anona diversifolia n sp. called izlama, or illamatzapotl, has flowers and fruit resembling those of *A. squamosa*, with the carpels not so closely united as in *A cherimolia*, and *A reticulata* It is distinguished from all other Mexican anonas by a large persistent orbicular, clasping bract at the base of the peduncle The type was collected by Dr Edward Palmer at Colima, Mexico, in 1897 (No 60)

W W STOCKBERGER,
Corresponding Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 689th meeting was held on February 11, 1911, President Day in the chair Two papers were read

Thermodynamics of Concentration Cells Dr HENRY S CARHART, of the University of Michigan

The paper was in illustration of the general equation expressing the laws of thermodynamics, of which the Helmholtz equation for the E M F of a voltaic cell is an example, viz

$$A = H + T(dA/dT),$$

in which H is the change in the internal energy of the system and A the maximum work or free energy for a reversible process conducted isothermally

A number of possible cases were outlined and two of them were emphasized for illustration and experimental verification

1 When H is constant Then $A = H + aT$ The relation is then linear and dA/dT is constant

2 If with Nernst ("Thermodynamics and Chemistry," *Sitzungsberichte der Kon Preuss Akad der Wiss*, 1909, 1, 247) it is assumed that H may be expressed in terms of the integral powers of T, then

$$H = H_0 + aT + bT^2 + cT^3 +$$

By integrating the general equation and substituting this value of H, it is proved that the constant a is zero and the two equations for A and H are

$$A = A_0 + a'T - bT^2 - \tfrac{1}{2}cT^3 -$$

$$H = H_0 + bT^2 + cT^3 +$$

Nernst assumes that $dA/dT = dH/dT = 0$ in the limit when $T = 0$ This condition would exclude the term $a'T$ and would exclude therefore the case where H is either zero or constant

An investigation of the concentration cell *Zn amal dilute/ZnSO$_4$ solution/Zn amal concen* gave the following data, which are best represented by the linear equation

$$E = -0\ 001455 + 0\ 00008084\ T\cdot$$

Temp	Obs'd E M F	Comp'd E M F	Per cent difference
11 1	0 007300	0 007307	+ 0 10
15 4	7444	7439	— 0 07
19 8	7574	7575	+ 0 01
24 6	7720	7723	+ 0 04
29 4	7870	7871	+ 0 01
32 8	7983	7976	— 0 09
36 6	8086	8094	+ 0 10
42 0	8262	8259	— 0 04
47 0	8417	8414	— 0 04

The greatest difference between the observed values and those computed by the above equation is 0 008 millivolt

The $ZnSO_4$ solution was then replaced by $ZnCl_2$ solution and the measurements were repeated. The results are best represented by the same equation within the limits of temperature 10° 1 and 49° 3 within which the observations were made Moreover, there is no break at the transition point of $ZnSO_4$ at 39° 0.

This relation is strictly linear and is directly and conclusively opposed to Nernst's assumption that the constant a and a' are both necessarily zero

Upon the Construction of the Wheatstone Bridge for Resistance Thermometers: Professor C F MARVIN, of the U S Weather Bureau

The speaker mentioned the well known fact that the resistance of metals such as platinum, nickel, etc, commonly employed in the construction of resistance thermometers, does not change with temperature according to a strictly linear law of relation, therefore, the scales of temperature obtained directly from resistance thermometers are not the same as the standard scale of temperature by the gas thermometer The object of the paper was to call attention to certain interesting mathematical relations between the bridge equations and those for platinum and nickel resistances, which, if availed of, enable the manufacturer to give the arms of the bridge such resistances that the indicated temperatures on the bridge scale correspond to the true temperature of the thermometer on the gas scale within a few hundredths of a degree over ordinary meteorological ranges of temperature, say from — 40° to + 60° Centigrade This result is obtained, moreover, when the subdivisions of the bridge scale are exactly equal throughout, and when the intervals of resistance on the bridge wire, or equivalent device, are made as exactly equal to each other as possible. Numerical data shown for nickel indicated that the logarithmic equation: $R = a + bt$ fitted the temperature resistance changes of some samples of nickel Other samples, however, require an equation of three terms, viz

$$\text{Log } R = a + bt - ct^2.$$

Diagrams and equations of bridges with the resistance placed in series with either the thermometer in the one case, or the balancing coil in the other, were explained

In all cases the bridge equations reduce to the general form $R = (A + Mt/N \pm t)$, in which A, M and N are constants fixing the numerical value of the resistances in the arms of the bridge The plus (+) sign applies when the shunted rheostat is in series with the balancing coil, and the equation then represents a curve, mathematically similar to a parabola, or a curve convex upward The equation with the minus (—) sign is required for the ordinary slide wire connections, and with the shunted rheostat in series with the thermometer In these cases the curve conforms very closely to the logarithmic or other curve *concave* upward

By computing the constants of the bridge equation from three points taken from the corresponding temperature resistance curve for the platinum or other thermometer that may be used, and then adjusting the resistances in the bridge accordingly, the indicated temperatures on the bridge are either identical with the gas-scale temperatures, or differ therefrom by only a few hundredths of a degree at the extremities of the range of eighty to one hundred degrees

Numerical examples were worked out and the resistances computed for the arms of the bridge to fit a platinum and a nickel thermometer. It was mentioned in the discussion that all of the equations apply equally to the case in which the differential galvanometer is employed instead of the bridge to determine the resistance of the thermometer

It is expected that this paper in full will be published in the *Journal of the Franklin Institute*

(The abstracts of the two foregoing papers are by their authors)

Professor Cleveland Abbe, of the U. S Weather Bureau, spoke informally concerning the altitude of the aurora, describing briefly Professor Störmer's recent successful method of measuring the altitude of an aurora, which consists essentially in simultaneously photographing the aurora from two points of known distance apart, some known star being also simultaneously photographed on the plates from which measurements can be made

THE BEGINNINGS OF INTELLIGENCE[1]

Nothing shews more the force of habit in reconciling us to any phenomenon, than this, that men are not astonish'd at the operations of their own reason, at the same time, that they admire the *instinct* of animals, and find a difficulty in explaining it, merely because it can not be reduc'd to the very same principles. To consider the matter aright, reason is nothing but a wonderful and unintelligible instinct in our souls, which carries us along a train of ideas, and endows them with particular qualities, according to their particular situations and relations.—David Hume, "Treatise on Human Nature."

We all have a certain curiosity regarding the evolutionary history of our various powers and attributes, but from many points of view an unusual interest attaches to the first development of intelligence. The word intelligence is used in a variety of senses by writers on comparative psychology and any discussion of the origin of intelligence would be fruitless unless the meaning in which the term is employed be understood. One of the foremost of comparative psychologists, the acute Father Wasmann, defines intelligence as "the power of conceiving the relation of concepts to one another and of drawing conclusions therefrom. It involves abstraction, deliberation and self-conscious activity." Intelligence, according to Wasmann, is the God-given attribute of man alone; its possession separates man from brute by an impassable barrier.

Many comparative psychologists, among whom we may mention Lloyd Morgan, Forel and Loeb, adopt as a criterion of intelligence the power of forming asso-

[1] Read before the meeting of the Sigma Xi of the University of California, December 7, 1910.

ciations, or associative memory, and we shall follow the usage of these writers. It is obvious that the possession of this faculty marks an important step in advance upon the creatures whose actions are fatally determined by their instinctive make-up. From its beginning in forms in which the simplest associations are established only after a large number of experiences, intelligence has assumed a rôle of ever-increasing importance in the evolution of animal life, until in man, who is notoriously a weakling compared with the large beasts with which he has had to contend it became the main factor to which the human species owes its supremacy in the struggle for existence

In considering the origin of intelligence one is naturally led to the subject of the relation of intelligence to instinct Formerly it was the custom to contrast these two faculties as if they represented diametrically opposed types of activity Instinct was regarded as something unalterably fixed, machine-like and practically perfect in its adaptation to the needs of the animal, intelligence was recognized as the antithesis of all these qualities—variable, plastic and eminently fallible. With the establishment of the theory of evolution writers became more disposed to discover the kinship and filiation of instinct and intelligence and they have given us a variety of views as to the relation of these faculties

Basing his theory on Lamarck's doctrine that instinct is inherited habit, G H Lewes attempted to explain instinct as "lapsed intelligence" Performances which are learned with difficulty come, after sufficient repetition, to be carried out automatically and without any intelligent guidance If the acquired facility of performing these acts is inherited and the acts are repeated generation after generation, it is probable that they might finally be performed by an individual without any previous instruction at all, that is, they would become instinctive. An animal's instincts, according to this view, represent the stereotyped and mechanized behavior which its ancestors found to be profitable; their adaptiveness rests upon the wisdom acquired by ancestral experience More recently this view has been upheld by Eimer, and in a less extreme form by Romanes, Wundt and many others

One difficulty with the theory of lapsed intelligence is that it involves the acceptance of the doctrine of the transmission of acquired characters, which has come to be a very questionable biological theory. But another and more fundamental difficulty is revealed by recent work on the behavior of lower organisms If instinct were derived from intelligence by a sort of mechanizing process we should expect, as Whitman has urged in his criticism of Lewes's theory, to find intelligence dominant in lower forms of life, and that acts which are instinctive in the higher animals would be intelligently performed by the lower ones The work that has been done on the behavior of lower organisms enables us to state with confidence that such is not the case. In several large phyla of the lower invertebrates there has not, as yet, been demonstrated the least glimmer of intelligence; and, as we pass up the scale of life, intelligence gradually supersedes instinct, not the reverse We can say with some degree of assurance that, however the transition may have been effected, intelligence has grown out of purely instinctive behavior

It is not possible, however, to fix, except with the rudest approximation, the stage of evolution at which intelligence makes its first appearance The transition from instinct to intelligence has been made in all probability, not once, merely, but several

times along different lines of descent. Intelligence in the vertebrates doubtless arose independently from that of the insects, and the intelligence exhibited here and there among the mollusks probably arose independently along a third line of development. Intelligence makes its appearance at a certain stage of organization along whatever line such a stage may have been reached.

Up to the point at which the power of associative memory becomes manifest there has been progress along many lines which has prepared the way for the evolution of this new faculty Behavior has not only become more complex, but it has become more plastic and capable of easy modification to suit new conditions The lower organisms do not always react in a particular way to a given stimulus What reaction occurs may depend upon the number of previous stimulations, the supply of food, exposure to different environing conditions, and numerous other factors which influence the internal state of the organism The behavior of many lower animals is plastic and adaptive to a remarkable degree, and to a superficial consideration often gives the appearance of a considerable degree of intelligence, without there being any detectable power of associative memory This plastic and varied behavior not only simulates intelligence, but it secures for the organisms many of the advantages which intelligence confers It adapts the animal to a more varied environment, and gives it the power of meeting a given situation in more than one way, so if one kind of response does not suit, another may be more successful Let us glance briefly at some of the ways in which behavior may be modified.

A very general change of behavior in its organisms consists in the habituation to any stimulus which is repeated at sufficiently close intervals so that the organism no longer responds to it This is shown even among the protozoa A *Stentor* or a *Loxophyllum* subjected to a light mechanical stimulus at short intervals soon fails to respond as at first, but the duration of the modification so produced is very short, in *Loxophyllum* it probably does not extend over two or three seconds Similar effects of repeated stimulation but of longer duration have been observed in *Hydra*, several species of sea-anemones, planarians, annelids and various other lower invertebrates As a rule failure to respond may occur more quickly and the effects of the stimulus remain longer as we pass up the scale of animal life

Occasionally the reverse phenomenon occurs when the response to a given stimulus is increased instead of diminished with repeated applications—a result which suggests the effect of the summation of stimuli At times, as Bohn found in *Cerianthus*, there is an initial increase of responsiveness followed by a dulling of sensitivity Bohn has attempted to subsume the effects of repeated stimulation under a general "law" to the effect that stimulation always produces at first increase of sensitivity to be followed later by a decrease Sometimes, as Bohn claims, the initial increase is so short as to escape detection, which may be true, but the burden of proof is on M Bohn

Repetition of a stimulus may call forth not only quantitative differences of response, but it may evoke responses of very different character. Animals are frequently provided with several modes of reacting to a given stimulus which may be called into play one after the other Jennings has shown that if a *Stentor* is subjected to a light mechanical stimulus by causing fine particles of India ink to fall upon its disk from a capillary pipette it

usually reacts first by bending a little to one side. If the particles continue to fall on the disk the beat of the cilia covering the body may suddenly be reversed, thus creating a current tending to carry the offending particles away. If in spite of this the particles still impinge upon the disk the *Stentor* may contract one or more times. Finally, if all these reactions are tried in vain the infusorian may give a number of violent contractions, break loose from its place of attachment, and swim away.

It would be an error to interpret the varied behavior of this unicellular organism as a manifestation of intelligence, although it is not unlike what the behavior of an intelligent creature might be under the circumstances. No power of learning by experience has ever been discovered in *Stentor*, or indeed in any other protozoan. The organism is provided with a number of different modes of response, and which one is set in action depends upon internal factors which are influenced by the creature's previous activity. The organism which has responded to a stimulus has become transformed into a different mechanism which may respond more or less readily than before or radically change its method of behavior.

A striking illustration of varied responses to a given stimulus has been described by Jennings in the sea anemone *Stoichactis*. If a foreign body is placed upon its disk the anemone tries to rid itself of the object in various ways. The tentacles near the object collapse and the area between them extends, thus producing a relatively smooth surface so that the waves can readily wash the object away. If this does not occur the region under the object begins to swell, thus rendering the removal of the object still easier. If this reaction is unsuccessful the edge of the disk begins to sink so that a smooth sloping surface is formed from which the object can readily slide. Here, as in the case of *Stentor*, we have an organism capable of reacting in several ways to a given stimulus. What particular reaction is evoked depends upon previous stimulations.

Modification of behavior caused by different conditions of nutrition are found in the lowest members of the animal kingdom. Even the white blood cells after they have ingested a number of bacteria refuse to take in more. Whether there is a limit to the appetite of *Amœba* has not been determined, but many infusorians such as *Stentor*, after having swept in a certain amount of food, react to food particles in a quite different way than when in a hungry condition. *Hydra* when not fed for some time extends the body, sways about in various directions and keeps up a restless movement of its tentacles, thereby increasing its chances of contact with the small creatures which serve as its prey.

Instances of the non-intelligent modifications of behavior might be multiplied indefinitely. As we pass to higher forms the capacity for responding in different ways to a given situation becomes greatly increased. "Nature," says James in his admirable chapter on instinct, "implants contrary impulses to act in many classes of things, and leaves it to slight alterations of the conditions of the individual case to decide which impulse shall carry the day;" and he points out that many animals lose the instinctive demeanor and appear to lead a life of hesitation and choice, not because they have no instincts, but because they have so many of them that they block one another's path. Intelligence in the acceptation of the term which we have accepted begins with the formation of associations. It does not make its appearance, so far as is known, until a comparatively

high stage of organization has been attained The evolution along the lines of complexity of instinct and ready modifiability of reactions to suit new conditions, affords a substantial basis for intelligent behavior. Without such evolution the power of associative memory would avail little But with a large number of readily modifiable instincts, associative memory becomes the means of affording a much wider and closer adjustment to the environment

The studies which have been made of primitive types of intelligence such as found in crustaceans, fishes and amphibians have shown that associations are formed by a gradual process of reinforcement or inhibition of a particular reaction to a given stimulus The method followed is one which Lloyd Morgan has designated as "trial and error" It may be illustrated by the experiment of Yerkes on the formation of associations in the crayfish. In these experiments a box was employed into one end of which the crayfish was admitted through a narrow aperture The other end of the box was divided by a median partition which gave the crayfish a choice of two routes to a tank of water at the other end into which the creature was naturally desirous of getting One of the two ways to the water was closed by a glass plate at its farther end so that the crayfish was afforded a choice of a right and a wrong path to the water. Would the crayfish after a number of trials learn to choose the right path and avoid the closed passage? In the first ten experiments the crayfish went as often to the right as it did to the left, but in the next ten trials the percentage of correct choices was somewhat greater. Finally after a large number of trials the animal came to choose the right path to the water, making but rarely any mistakes

Similar experiments with crabs, fishes and the frog have yielded similar indications of slow learning. In some respects such learning resembles the slow formation of a habit rather than the judgment of a consciousness which "sizes up" the situation and determines upon a certain course of action. It is quite probable that such a primitive form of learning does not include any association of ideas It can be satisfactorily accounted for by assuming nothing more than an association of certain sense perceptions with particular movements The animal may have no ideas to associate—nothing but sense impressions and motor impulses Of course its mental content *may* include much more than this, but in interpreting the behavior of animals it is generally advantageous to follow the principle laid down by Lloyd Morgan—which is a sort of special application of the law of parsimony—that we should not assume the existence of a higher psychic function if the phenomena can be explained as well in terms of a lower one.

The step from sensori-motor association to the association of ideas is not, I believe, a wide one, and comes abont as a natural consequence of the elaborateness and what Hobhouse has designated as the "articulateness" of the mental process of adjustment It is foreign to our purpose, however, to trace the increase in the number, delicacy, quickness and complexity of the processes of association which we meet in the various stages of mental evolution One problem at present lies in the initial step involved in the formation of a simple association And it is a problem which, despite its apparent simplicity, involves the consideration of some vexed and subtle questions.

In learning we have to do with two opposite processes of reinforcement and inhibition. A chick after it pecks at a caterpillar which is wholesome and savory pecks

at a similar caterpillar more readily on a second occasion. Something has apparently reinforced the connection between the visual impression produced by the caterpillar and the pecking impulse. If, on the other hand, the chick pecks at a caterpillar having a nasty taste it is apt to avoid pecking at it a second time. Something has happened to inhibit the response that would otherwise occur. We commonly explain such behavior by ascribing to the creature feelings of pleasure and pain. We say that the chick pecks at one kind of a caterpillar because of the pleasant taste it derives, and avoids another variety because its taste is bad. Pleasure and pain apparently function as agents for the reinforcement of certain reactions and the stamping out of others. It is a general rule, though not without certain exceptions, that what affords pleasure is conducive to organic welfare, while that which is productive of pain is injurious. The upshot is that the associations that are the outcome of the pleasure-pain response are of just the kind that minister to the animals' needs. Beneficent arrangement! Apparently we have to do with a selective agency which preserves and intensifies certain kinds of behavior and rejects others on the basis of their results—a kind of "sorting demon" in the realm of behavior. What could be more teleological!

The fact that what is pleasant is usually beneficial and what is painful is usually injurious may be explained with some plausibility as the result of natural selection, as was first contended by Herbert Spencer. Animals which took pleasure in doing things which were bad for them and which experienced pain in doing things which were good for them would be very apt to fare ill in the struggle for existence. Natural selection would ever tend to bring about a condition in which the pleasant means the organically good and the painful means the reverse. We should not expect the correspondence, if brought about in this way, to be complete, and it is rather in favor of the theory that we do not find it so.

But granting this contention of Spencer, there is the important question still left unanswered, namely, Why do animals follow what is pleasant and avoid what is painful? In other words, why does pleasure reinforce and why does pain inhibit? Here is another fundamental problem and we find that Spencer with his usual appreciation of fundamental problems was on the ground early with a theory. Pleasure, according to Spencer, is the concomitant of a heightened nervous discharge, pain the concomitant of a lessened nervous discharge. An act which brings pleasure causes an influx of nervous energy to the centers concerned in the movement, the lines of discharge become "more permeable," and upon a repetition of the conditions the same act follows with greater readiness than before. If the act is followed by pain with its concomitant of lessened nervous discharge, the diminution of nervous energy serves to prevent the performance of the act in response to the same conditions. Closely similar explanations of the physiology of the pleasure-pain response have been given by Bain and by Baldwin, the latter declaring that "pleasure and pain can be agents of accommodation and development only if the one, pleasure, carry with it the phenomenon of motor excess—and the other, pain, the reverse—probably some form of inhibition or of antagonistic contraction."

The physiological concomitants of pleasure and pain have afforded a subject for numerous laboratory studies and almost no end of theories. It has been impossible thus far to discover that either of these states is invariably accompanied by any

definite physiological condition The theory of Spencer and Bain is open to obvious criticism, for the man who steps on a tack undoubtedly has a "heightened nervous discharge," as much as a man who shouts for joy And I believe I am safe in saying that no theory of the physiology of pleasure and pain is on a sufficiently firm basis to warrant its being regarded as anything more than a very tentative working hypothesis

With our present knowledge of the psycho-physiology of pleasure and pain, the attempt to explain how these states or their physiological concomitants, whatever they may be, can act as agents of reinforcement and inhibition seems rather a fruitless one The process which we meet at the beginning of intelligence in simple associative memory may be formulated as follows

stimulus — reaction — pleasure — reinforcement
physiological state x
stimulus — reaction — pain — inhibition
physiological state y

Spencer, Bain and others have endeavored to show how the organic accompaniments of pleasure and pains modify the creatures' subsequent responses But as the problem was interrupted by these writers our ignorance concerning the physiological states x and y brings us to a standstill.

In his valuable work on "Mind in Evolution" Hobhouse has presented a new point of view in considering this problem, which has the advantage of not involving any general theory of the physiology of pleasure and pain It is essentially a theory of how behavior comes to be adaptively modified through the formation of associations It makes no attempt to explain why pleasure is associated with certain experiences and pain with others. Such association may turn out to be as inexplicable as the problem why stimulation of the optic nerve gives rise to a sensation of light instead of some other kind of feeling What it is feasible to attempt to explain is why certain responses tend to be repeated and others tend to be inhibited And this can be explained with some plausibility as due to the congruity or incongruity of the reactions which come to be associated For the sake of illustration let us consider again the chick which pecks at a nasty caterpillar The irritation set up by the caterpillar in the chick's mouth evokes movements of withdrawal and ejection The two responses of pecking and ejection become associated, but as the two movements are contradictory the result is inhibition The pecking reaction no longer occurs in the presence of a second nasty caterpillar, not because of any stamping-out influence of the physiological concomitant of pain, but because it becomes joined with an antagonistic reaction

In a previous paper by the writer the attempt was made to extend the theory of Hobhouse to account for the reinforcement commonly held to be caused by pleasure. The assumption was made that this process is due to an organic congruity of the reactions If the caterpillar pecked at is a savory one there is set up the reflex of swallowing Pecking and swallowing form the normal elements of a chain reflex, when one part of the structure concerned is excited it tends to increase the tonus of the associated parts, and thus reinforce the original response I have found that in the crayfish stimulation of the antennules, which are important organs of smell, sets up chewing movements of the mouth parts and grasping movements of the small chelæ Similarly stimulating the small chelæ evokes chewing movements of the mouth parts and twitching of the antennules, while stimulating the mouth parts

directly may cause movements in both the other sets of organs. We have here as a matter of fact a number of reflexes which mutually reinforce one another. Suppose that in the chick the sight-pecking response and the taste-swallowing response are related as the feeding reflexes demonstrably are in the crayfish, the second response would thus tend to reinforce the first, and if this tendency persisted we would have a case of learning by experience

Animals in the course of their instinctive responses encounter stimuli which bring about other responses These become associated According to the nature of the nervous pathways involved, there may be reinforcement of or interference with the original reaction Experience brings about an extension of the range of adaptations by the assimilation of congruent reactions and the elimination of acts whose secondary consequences are in the nature of antagonistic and thereby inhibitory responses Such we may say, by way of expressing a tentative view-point, is the nature of primitive intelligence

But it will be seen that the capacity to form new adaptations rests upon the primary adaptiveness of the instinctive reactions. The power of formation of associations alone would never lead to improvement The adaptiveness of intelligence is based upon the adaptiveness of instinct, it may be said that intelligence is a means of enabling an animal to live its life more completely and successfully, but instinct furnishes the fundamental springs of action Even complex creatures like ourselves form no exception to this rule.

S. J. HOLMES

UNIVERSITY OF WISCONSIN

THE GALTON CHAIR OF EUGENICS

WE have noted that Sir Francis Galton, F.R.S., who died on January 17, aged 88, had left his residuary estate to the University of London for work in eugenics This residuary estate will amount to about £45,000 In his will Sir Francis Galton describes the scope of his new foundation as follows

I devise and bequeath all the residue of my estate and effects, both real and personal, unto the University of London for the establishment and endowment of a professorship at the said university to be known as "The Galton Professorship of Eugenics," with a laboratory or office and library attached thereto And I declare that the duty of the professor shall be to pursue the study and further the knowledge of national eugenics—that is, of the agencies under social control that may improve or impair the racial faculties of future generations physically and mentally And for this purpose I desire that the university shall, out of the income of the above endowment, provide the salaries of the professor and of such assistants as the senate may think necessary, and that the professor shall do the following acts and things, namely

1 Collect materials bearing on eugenics

2 Discuss such materials and draw conclusions

3 Form a central office to provide information, under appropriate restrictions, to private individuals and to public authorities concerning the laws of inheritance in man, and to urge the conclusions as to social conduct which follow from such laws

4 Extend the knowledge of eugenics by all or any of the following means, namely (*a*) professorial instruction, (*b*) occasional publications; (*c*) occasional public lectures, (*d*) experimental or observational work which may throw light on eugenic problems

He shall also submit from time to time reports of the work done to the authorities of the said university.

I also declare that the said university shall be at liberty to apply either the capital or income of the said moneys for any of the purposes aforesaid, but it is my hope that the university will see fit to preserve the capital thereof wholly or almost wholly intact, not encroaching materially upon it for cost of building, fittings or library Also that the university will supply the laboratory or office at such place as its senate shall from time to time determine, but preferably in the first instance in proximity to the Biometric Laboratory. I state these hopes on the chance of their having a moral effect upon the future decisions of the senate of the university, but they are not intended to have

any legally binding effect whatever upon the freedom of their action. And I declare that it shall be lawful for the senate of the said university, if they shall think fit so to do, to postpone the election of the first or any subsequent professor of eugenics for a period of not exceeding four years from the date of my death, or from the date of the occurrence of any vacancy in the office as the case may be . .

I declare it to be my wish, but I do not impose it as an obligation, that on the appointment of the first professor the post shall be offered to Professor Karl Pearson, and on such conditions as will give him liberty to continue his Biometric Laboratory now established at University College

SCIENTIFIC NOTES AND NEWS

THE National Academy of Sciences will hold its annual meeting in Washington, beginning on Tuesday, April 18

THE American Philosophical Society will hold its general meeting in the hall of the society at Philadelphia on April 20, 21 and 22 On the evening of April 21, Professor Svante Arrhenius, of Stockholm, will give an illustrated lecture on the physical condition of the planet Mars, which will be followed by a reception in the hall of the College of Physicians. On the evening of the twenty-third the annual dinner of the society will take place at the Bellevue-Stratford

DR WILLIAM H WELCH, professor of pathology in the Johns Hopkins University, has received from the emperor of Germany the decoration of the royal crown of Prussia, second class.

DR. LEWIS BOSS, director of the Dudley Observatory and of the department of meridian astronomy of the Carnegie Institution, has been elected a corresponding member of the Academy of Sciences of St. Petersburg

DR. S. W. STRATTON, director of the Bureau of Standards, represents the United States government at the International Convention on Weights and Measures at Paris, beginning on March 29.

PROFESSOR ALBERT A. MICHELSON, head of the department of physics in the University of Chicago, will give a course at the University of Gottingen in the coming summer semester.

AT the invitation of the Department of Education of the Philippine government, Professor J Paul Goode, representing the University of Chicago, will deliver a series of lectures to the Teachers' Assembly at Bagino in May

THE expedition that was sent to Argentina two years and a half ago under the auspices of the Carnegie Institution for the purpose of making meridian measurements of position of stars down to the seventh magnitude that are south of $-20°$ of declination, and generally inaccessible for exact measurement at observatories of the northern hemisphere, has completed its meridian-work In 1909 and 1910 about 87,000 meridian-determinations of positions were made with precision The observations were conducted on a fundamental basis, and correspond to others to be secured at the Dudley Observatory at Albany as an integral part of the entire enterprise The instruments were shipped to Albany from Buenos Aires early in March and the members of the staff, of which Professor Richard H. Tucker is director, are arriving at various times

THE magnetic survey yacht the *Carnegie* arrived at Capetown on March 20, having completed successfully a voyage of about 14,000 miles in the Atlantic Ocean since last June Dr Bauer left Vancouver on March 24 to make magnetic observations in the Samoan Islands during the total solar eclipse of April 28 and to meet the *Carnegie* at Colombo, Ceylon

IT is stated in *Nature* that at the recent meeting of the Australasian Association for the Advancement of Science in Sydney, the Mueller memorial medal was awarded to Mr. Robert Etheridge, curator of the Australian Museum, in recognition of the value of his numerous contributions to the paleontology and ethnology of Australasia.

THE trustees of Dartmouth College have voted that Charles Henry Hitchcock be made Hall professor of geology, emeritus, and that Gabriel Campbell be made Stone professor of

intellectual and moral philosophy, emeritus. They retired last year on the Carnegie Foundation fund. Frank Asbury Sherman, professor of mathematics, will retire at the end of the academic year, when he will have reached the age of sixty-nine years.

PROFESSOR BERNSTEIN, director of the physiological laboratory at Halle, will retire from active service at the beginning of the winter semester on account of advanced age.

DR. ROLLIN T. CHAMBERLIN, of the University of Chicago, sailed for South America on March 20, to engage in geological work on some of the metamorphic rocks of southeastern Brazil and on certain portions of the Andes.

DR. SIMON B. WOLBACH, assistant professor of bacteriology at the Harvard Medical School, and Dr. J. L. Todd, of McGill University, have departed for West Africa to study the sleeping sickness and allied diseases.

DR. A. S. PEARSE will leave the University of Michigan on April 1, to fill a position as assistant professor in the department of zoology of the University of the Philippines in Manila.

DR. ÖSTEN BERGSTRAND, for some time observer at the Upsala Observatory, Sweden, has been appointed professor of astronomy in the Upsala University and director of the observatory.

DR. SVANTE ARRHENIUS, director of the Nobel Institute, Stockholm, lectured before the Washington Academy of Sciences and the Philosophical Society of Washington on March 25 on "The Siderial Cultus."

DEAN ALLEN J. SMITH, of the University of Pennsylvania, closed a series of popular health lectures, given under the auspices of the medical faculty, March 17. His talk was on "Flies and Other Insects as Carriers of Disease."

ON the evening of March 17, Professor C. J. Keyser, of Columbia University, delivered a lecture before the Philosophical Club of Princeton University on "The Nature and Philosophic Significance of the Mathematical Doctrine of Invariance."

MR. JAMES R. STEERS, of the class of 1853, has made a further gift of $2,200 to the Wolcott Gibbs Library of Chemistry of the College of the City of New York. The money is to be expended in the completion of certain journals and for cataloguing.

A PORTRAIT of David Rittenhouse, painted in 1772 by Rembrandt Peale, has been given to the University of Pennsylvania by Mrs. William Lawber. David Rittenhouse was professor of astronomy and vice-provost of the university from 1779 to 1782, and from 1782 until the time of his death in 1796, a trustee.

FÉLIX PLATEAU, who recently retired from active duties of the chair of zoology in the University of Genth, known especially for his studies on the behavior of insects, died on March 4.

IN the New York senate on March 21 a bill was introduced to incorporate "The Carnegie Corporation of New York." The incorporators named in the bill are Andrew Carnegie, Senator Elihu Root, president of the Carnegie Endowment for International Peace, Dr. Henry S. Pritchett, president of the Carnegie Foundation for the Advancement of Teaching, William H. Frew, president of the board of trustees of the Carnegie Institute of Pittsburgh, Robert S. Woodward, president of the Carnegie Institution of Washington, Charles L. Taylor, president of the Carnegie Hero Fund Commission; Robert A. Franks, president of the Home Trust Company, and James Bertram, Mr. Carnegie's secretary. Under the language of the bill the incorporators are authorized "to receive and maintain a fund and apply the income to promote the advancement and diffusion of knowledge among the people of the United States, by aiding technical schools, institutions of higher learning, libraries, scientific research, hero funds, useful publications, and by such other agencies and means as shall from time to time be found appropriate."

THE Austrian Academy of Sciences held on March 9 a sitting to celebrate the fiftieth anniversary of the appointment of the Archduke Rainer to be its curator. The archduke gave 100,000 kronen to the academy as an en-

dowment to keep the academy in touch with the progress of science abroad

M FAUVEL has offered 30,000 francs for the construction of an addition to the laboratory of the National Museum of Natural History in Paris

THE president of the Royal Society and the members of the General Board of the National Physical Laboratory visited the laboratory on March 17

AT midnight on March 10 the clocks at the railway stations and all government offices and municipal buildings of France and Algeria were set back nine minutes twenty-one seconds, to bring them in accord with Greenwich time, which is now used in all countries of western Europe except Russia, Portugal and Ireland

THE ninth International Congress of Agriculture will be held at Madrid, beginning on May 8, under the patronage of his Majesty Alfonzo XIII Americans wishing to attend the congress may secure the printed account of the arrangements from the American member of the *Commission Internationale d'Agriculture*, Dr L O Howard, U S Department of Agriculture, Washington, D C

THE next triennial prize of £300, under the will of the late Sir Astley P Cooper, will be awarded to the author of the best essay or treatise on "The Means by which the Coagulability of the Blood may be Altered" Essays, written in English, must be sent to Guy's Hospital, before January 1, 1913

THE U S Civil Service Commission announces an examination on April 15, to fill at least three vacancies in the position of magnetic observer in the Coast and Geodetic Survey The initial salaries will range from $75 to $90 a month, according to the character of the work and the qualifications of the applicant; and in exceptional cases where the person employed has had repeated experience in magnetic work, the initial salary may reach $125 a month. Appointments to permanent positions are also made from the examination for laboratory assistant in the Bureau of Standards

THE Harpswell Laboratory will be open this summer for the fourteenth season, from June 19 to September 15 South Harpswell is 16 miles from Portland, Maine, with which it is connected by several boats daily The location is admirably adapted for a biological station It has a very rich marine flora and fauna Especially noteworthy are the abundance of Elasmobranch material, and the eggs of *Cerebratulus* and *Echinarachnius*, so valuable for experimental studies For several years the laboratory has been open solely for research, no instruction being given It has nine private rooms, several of which are already engaged for the coming summer, and can accommodate a few more in the large laboratory room Thanks to the cooperation of several colleges and universities, the laboratory is able to offer its facilities free to those competent to carry on independent investigation There will be a collector employed and the laboratory has several boats, including a motor boat, dredges, the usual instruments and glass ware and a little physiological apparatus Alcohol for collections and expensive chemicals can not be furnished There is also a small library The laboratory will not issue a circular this year Those wishing to avail themselves of its facilities should apply to Professor J S Kingsley, Tufts College, Mass It would be well to give some idea of the line of work to be followed so that advice may be given as to the prospects of material

BY cooperation between the American Museum of Natural History and the United States Bureau of Fisheries, the government steamer *Albatross* sailed from San Diego, on February 25, on a two months' collecting expedition to Lower California Dr. Charles H. Townsend, acting director of the museum, is in command of the expedition He is accompanied by seven investigators and collectors, representing the U. S National Museum, the New York Zoological Society and the New York Botanical Gardens, all of which bear a share of the expense of the trip Dr Townsend began the work with a line of deep-sea dredgings to Guadalupe Island, some two

hundred and fifty miles from San Diego From Guadalupe Island the *Albatross* planned to work eastward to begin a fish survey of the peninsula of Lower California. The fishery resources of the region will be studied with a view to the establishment of closer fishery relations with Mexico There will be work on shore also The peninsula is seven hundred and fifty miles long and will be studied along both coasts During the progress of the vessel along these coasts collecting parties will be landed each day to procure the mammals, birds, reptiles and fishes of the region, which are of especial interest to naturalists because so large a number of them are peculiar to the locality

THE Charleston (S. C) Museum has been developing a large amount of public interest recently in the scientific studies that were so much cultivated in that city in the years before the war In the middle decades of the last century, Charleston was a center of scientific work and interest The visit there of Agassiz in 1850, and the notable work of Audubon and Bachman, and of others beside, gave great stimulus to scientific pursuits There has been organized in recent years a Natural History Society, as an educational department of the museum, composed largely of young people, but by no means confined to them, which has already done much excellent local work, and is raising up and training a body of enthusiastic observers, especially in botany and ornithology The museum has also within the past year issued the first volume of its "Contributions,"—"The Birds of South Carolina," by Arthur Trezevant Wayne, honorary curator of ornithology in the museum, and a recognized authority on the birds of the region This is an octavo volume of 254 pages, and is the most complete and accurate work on the subject that has been published With a view to stimulating public interest, and also in the desire to link the present and future work of the museum with that which gave Charleston its reputation in the days of Audubon and Bachman, the Natural History Society proposed to devote its March meeting to the work of those eminent men, and to make it a memorial occasion To this end, request was made for copies in private hands, of the plates and various editions of their works, and also for other objects connected with them The main hall of the museum was assigned to this Audubon-Bachman exhibit The result exceeded all anticipation, and revealed a wealth of choice material of this kind, belonging to private owners that had not been suspected A noble collection of Audubon's bird-plates was thus secured, together with copies of the several editions of his work on birds, and of the joint work of Dr. Bachman on the mammals, with busts, portraits, original drawings, etc., of great interest This loan collection attracted much public attention, and has given a distinct impetus to scientific appreciation in the city At the memorial meeting, held on March 2, a large audience was present, and very interesting addresses were given on the life and work of both Audubon and Bachman, by several speakers, including Director Rea, of the Museum, and the venerable Dr C S Vedder, of Charleston, an intimate friend of Dr Bachman for many years

A NEW expedition is being arranged, Reuter's Agency learns, to explore the Snow Mountains of New Guinea, a region in which the British expedition under Captain Rawling is at present working The Dutch government is interested in the undertaking, and Queen Wilhelmina and Prince Henry have contributed towards the cost. The details have not yet been finally arranged, but it is probable that Captain von Nauhuys, who has already been on three expeditions in New Guinea under Dr. Lorentz, will be in command and will be accompanied by a number of European scientific men.

THE production of tungsten in the United States increased considerably during the year 1909, but practically all the nickel, cobalt and tin consumed was imported. In an advance chapter from "Mineral Resources of the United States Calendar Year 1909," prepared by Frank L. Hess for the United States Geological Survey, the production of these metals and of the rarer metals vanadium, titanium,

molybdenum, uranium and tantalum is reported. Colorado led in the production of tungsten in 1909 The prices quoted for the metal were considerably higher than in 1908, and the production of ore increased from 671 short tons, valued at $229,955, to 1,619 tons, valued at $614,870. This is the largest quantity produced by any country in one year The United States last year produced nearly one third of the world's total production of tungsten ore, which was about 5,300 tons Very little nickel was produced in the United States, but a great deal was imported, and, as more nickel is refined in this country than can be used here, large quantities were exported In all, 22,194,102 pounds of nickel as metal and as metallic content of ores were brought into the United States in 1909 The total value was $3,036,273 The exports of nickel amounted to 12,048,737 pounds, valued at $4,101,976 The importations of cobalt amounted to 12,132 pounds, valued at $11,696 Titanium is being used with great success in making steel rails The New York Central Line has given rails treated with ferrotitanium a thorough test in the Grand Central terminal yards and now requires that all rails made for its lines shall be treated with titanium alloy. Rutile, or titanium oxide, was produced in the United States last year only at and near Roseland, Va No rutile was imported, but one American company exported it in considerable quantities Molybdenum, uranium and tantalum were little used in the United States in 1909, and only a small quantity of tantalum was produced A little was imported from Germany, but the use of tungsten in incandescent lamps has proved so satisfactory that the demand for tantalum has probably not greatly increased Although the United States uses 43 per cent. of the world's output of tin, it is not an important producer of that metal. Tin was produced in Alaska and South Dakota in 1909, but not in large quantities. In 1909 there were imported into the United States 47,662 tons of tin, valued at $27,558,546. The average price was 28.91 cents a pound. Several thousand tons of tin are recovered from used tin cans and other wastes.

UNIVERSITY AND EDUCATIONAL NEWS

THE subscription to the memorial to President Grover Cleveland exceeded $100,000 on the seventy-fourth anniversary of his birth It will be remembered that the memorial is to be a tower forming part of the graduate college of Princeton University

THE University of Washington at Seattle has received from Messrs Sigmund and Abraham Schwabacher $30,000 to maintain a bureau of child welfare

GOVERNOR STUBBS, of Kansas, has vetoed the bill placing the University of Kansas and other state institutions under the control of a commission consisting of three paid members It is stated that the recent legislature seriously reduced the appropriations for the university

THE University of the Pacific, College Park, California, by the action of its trustees, will henceforth be known as the College of the Pacific This action separates the college from a conservatory of music and a preparatory department.

AT the meeting of the board of regents of the University of Minnesota on March 3, the salary of one of the professors, who is dean of one of the schools, was increased from $4,000 to $6,000

THE cornerstone of the administration building of the William M Rice Institute, was laid by the trustees on March 2, the seventy-fifth anniversary of Texan independence The seven members of the board were present. They are: J. A Baker, W. M. Rice, Jr., J. E McAshan, B. B Rice, C. Lombardi, E. Raphael, E O Lovett.

HEREAFTER the degree of bachelor of chemistry (B Chem.) will be conferred by Cornell University on students who have completed the special course in chemistry The department of chemistry remains a department of the College of Arts and Sciences. A four-year course in chemistry and allied subjects has been offered by the department since about 1903 for students planning to follow chemistry as a profession. Although the course is essentially technical in character and professional in purpose, the degree of bachelor

of arts, has heretofore been conferred upon its graduates

AT Smith College Harriet W Bigelow has been promoted to be professor of astronomy, and Frances Grace Smith to be associate professor of botany

AT Yale University Dr Alexander Petrunkevitch has been promoted to be assistant professor of zoology, and Dr Carl Johns, to be assistant professor of chemistry

DISCUSSION AND CORRESPONDENCE

THE AIR WE BREATHE

TO THE EDITOR OF SCIENCE As a member of the American Society of Heating and Ventilating Engineers, who had the pleasure of hearing the recent address of Dr. Gulick before that society, I desire to reply to his letter in SCIENCE of March 3 I believe that Dr Gulick is engaged in a research whose results may be of the utmost importance to the health of a large fraction of the human race—namely, the children in the schools—and it is to be desired that he be given every encouragement to continue in it

First, to answer some of his questions in regard to the physics of atmospheric air. No one knows "the reason why" raising the temperature of air increases its capacity for holding moisture It is merely one of the great facts of nature, like gravitation, and like the fact that water freezes at 32° F At 32° F. a cubic foot of air has the capacity of holding in a gaseous condition 0 0003 pound of water, at 62°, 0 00087 pound, at 72°, 0.00121 pound, at 102°, 0 003 pound, and so on

"Is there any difference between steam and humidity?" Steam is water in a gaseous state There is no difference between steam and the gaseous or uncondensed vapor of water in the atmosphere. When steam escapes from a pipe into an atmosphere colder than itself it condenses into fog, which is visible, but if the atmosphere is not saturated with moisture it will rapidly dry the fog, turning it again into invisible vapor Humidity is the condition of the atmosphere as regards moisture. Relative humidity is the ratio or percentage that the moisture contained in the atmosphere bears to the maximum quantity it can contain at the same temperature Thus if a cubic foot of air at 62° contains 0 00087 pound of water vapor, the air is "saturated" and the relative humidity is 100 per cent, but if the same quantity of moisture is contained in a cubic foot of air at 72° the relative humidity is only 0 00087 — 0 00121 or 72 per cent

"The manuals of the heating and ventilating engineers tell us that with a good system of ventilation the opening of windows causes only danger, yet as a matter of fact, children in rooms so treated do not exhibit the distressing conditions," etc

The "danger" from opening windows is not to the children in the room in which the windows are opened, but to the children in the adjoining rooms in which the windows are not opened In the fan-blower or "plenum" system of ventilation the entrance and exit flues and dampers are so designed and adjusted as to cause each room to receive its due proportion of the total air supply If a window is opened in one room (unless the wind is blowing towards the window) the resistance to the passage of air from the room will be less than if only the exit flue were open, consequently there will be a lower static pressure in this room than in the other rooms, and it will receive from the entrance flue more than its proper share, thus robbing one or more of the other rooms of their share The flow of air in a complex system of piping is like the flow of water. If in an apartment house with ordinary plumbing a tenant on a lower floor draws hot water into a bath tub, he will rob the bath room on the floor above of its hot water supply for the time being. So in a school-house fitted with air pipes, if the flow of air from the fan into one room is increased by opening a window, there will be a smaller supply for the other rooms. The "danger" therefore is that of unbalancing the ventilating system. This danger would be avoided if there were in use an automatic ar-

rangement for closing the damper of the admission flue every time a window was opened

The science of heating and ventilation may be divided into two branches (1) hygiene, (2) engineering The first includes the knowledge of the effect upon health and physical and mental vigor of the condition of the air in buildings as regards temperature, relative humidity, content of CO_2 and other noxious gases, etc The second includes the knowledge of how to design, install and operate apparatus which will maintain the conditions that are desired The engineering branch of the science is in fairly good shape. If the temperature, humidity and CO_2 desired in a given school room are specified, the engineers can furnish apparatus which will meet the specifications, and whether or not the specifications are fulfilled can be tested by means of thermometers, hygrometers and analyses of the air in the rooms The hygienic branch, however, is in a very poor shape It is for the doctors to settle, and not for the engineers.

In Dr Gulick's address he threw doubts "upon the very foundations upon which the science of heating and ventilation is built," that is, the hygienic foundations He doubts, I understand, if it is necessary to supply sufficient air to keep the CO_2 down to 8 parts in 10,000, the recognized standard All that the engineers know is that there is a tradition, handed down in the text-books from time immemorial, that the CO_2 should not exceed this limit, and on the generally accepted statements that a man will exhale on the average 0 6 cubic foot of CO_2 per hour, and that the outside air contains about 4 parts in 10,000, the requirement will be met by furnishing 1,500 cubic feet of air per hour to each inmate To be on the safe side, the school authorities in Massachusetts many years ago, placed in their code the specification that 1,800 cubic feet per hour should be supplied for each pupil, and this requirement has been placed in the statute laws of several states.

As to the desired temperature and humidity, and as to the desirability of having artificial ventilation at all, the doctors disagree. Dr. Gulick's letter states that Doctors Thompson and Brennan "think we ought to do away all systems of ventilation, and use simply natural ventilation—open windows," while Dr Leonard Hill has found an "admirable result" from a plenum system, giving a moving air at 57–60° F and about 70 per cent relative humidity with all windows and doors kept closed Both of these ideas are opposed to the modern American system, which is a plenum system maintaining a temperature of 70° F, letting the humidity be what it may, with no attempt to control it A relative humidity of 70 per cent at 60° F is about equivalent in actual quantity of moisture to 50 per cent at 70° F, and this is probably much greater than the humidity in New York schools in clear cold weather

The temperature that is desirable in school rooms is probably largely a matter of habit and local custom Our people are accustomed to a room temperature of 68–72°, and think they like it Englishmen in their own country profess to like 58-62° Which is actually the best temperature, or whether the higher temperature is better here and the lower in England probably no one knows. As to the effect of humidity at temperatures between 58° and 72° F does any one really know? We do know that high humidity at 80° is much more uncomfortable than low humidity at 90°, and we know also that regions of low humidity are famous as health resorts

There is a vast amount of ignorance as to the hygiene of ventilation. Dr Gulick seems to have an arsenal of facts (?) and a body of "as yet undigested information" on the subject, and it is to be hoped that he will correlate and digest them, and present them in digested form before some learned society and have them discussed and printed for the public benefit I venture the opinion, however, that all the investigations by the authorities he names, after being correlated and digested, are insufficient in extent and not sufficiently scientific in quality to form the basis of a final judgment on the disputed questions in the hygiene of ventilation.

What is needed is a new research, aided by all the facilities of modern science and instru-

ments, under the auspices of the Carnegie Institution or the Russell Sage Foundation, to discover by direct experiment on a large scale, the effect upon the health and comfort of school children, of the three different systems of ventilation: (A) Open windows, as recommended by Doctors Thompson and Brennan, (B) the plenum system recommended by Dr. Hill, with low temperature and high humidity, (C) the American plenum system with 70° temperature and low humidity.

For the carrying out of a portion of the research, I suggest that experiments be made in several rooms of a large grammar school, all with the same window exposure and light, one room being treated by direct radiation and all ventilation obtained by open windows, and others by the plenum system, with the volume, temperature and humidity regulated at will. Let the rooms be thoroughly aired, say from 8 to 8.30 A.M., then when the children enter at 9 A.M. have their condition noted by trained specialists, with all the known pathologic and psychopathic tests, including the use of instruments for recording the pulse and the respiration, "reaction time," etc., and let these tests be repeated at noon. Tests should also be made to determine relative mental fatigue, lack of attention, etc. Statistics should be collected to determine what relation, if any, exists between the ventilating system or quality and quantity of ventilation in the schools and the prevalence of adenoids, sore-throat, headache, colds, etc. It may be found that these troubles have relation to the environment of the child during the nineteen hours that he is out of school rather than the five hours that he is in school.

Experiments should be made to find whether the percentage of CO_2 in the school room has the relation to the child's health or mental vigor that it has been commonly supposed to have, and whether an air supply of 600 or 1,200 cubic feet per hour per pupil, instead of 1,800, produces any bad effects. Bacterial examination of the air should be made at the same time.

Such a research as is suggested will take a long time and will cost much money, but is there any investigation now under way that is more worth the money, or that promises more for the welfare of the race?

WILLIAM KENT

TO THE EDITOR OF SCIENCE: I am writing in the endeavor to clear up some of the elementary questions asked by Dr. Luther H. Gulick in his letter "The Air We Breathe," published in SCIENCE of March 3.

When air is completely saturated with water vapor, the humidity in it is vapor, that is, a gas at point of condensation. At other times humidity is a gas, just as much so as CO_2, it is in fact superheated steam in the air. A gas just ready to condense to liquid is called vapor; thus, ordinary steam is a vapor, while superheated steam is a gas, obeying all the well-known gas laws. Humidity is a vapor whenever the air is completely saturated, being then the same as ordinary steam in the air, when, as is usually the case, air is unsaturated, then humidity is superheated steam in the air—a gas. Heat added to vapor superheats it, that is, raises its temperature. Heat taken from vapor condenses some of the vapor to liquid without altering the temperature.

Liquids remain in the liquid state only by virtue of external pressure exerted upon them, and any liquid will quickly turn to gas if all external pressure (which is usually that exerted by the atmosphere) is removed; the tendency for a liquid to gasify depends upon the temperature and kind of liquid, and nothing else.

If a closed vessel containing water and air is let stand at any temperature until conditions have become constant the air will gradually become saturated with water vapor, and the amount of water vapor that will be thus absorbed by a given volume of air will depend only on the temperature of the air, it would, moreover, practically be not only independent of the pressure of the air, but would be the same if another gas or even a vacuum were substituted for the air; also the pressure exerted by the water vapor filling the given space at a given temperature would be the same in all these instances.

In a gas mixture the total pressure exerted by the mixture upon the walls of a containing

vessel is the sum of the pressures exerted by the individual gases composing the mixture, thus, air is a mixture of oxygen, nitrogen, CO_2, superheated water vapor and many other so-called rare gases, and the atmospheric pressure is the sum of all the pressures exerted individually by all these gases

Take again the closed vessel containing water and air; the quantity of water vapor per cubic foot of space above the water, as well as the pressure exerted by this water-vapor, conditions having become constant, will always be the same for the same temperature, but will rapidly increase with rise of temperature The following tabulation shows the maximum capacity of air (or other gas or better simply of space) for water vapor at different temperatures, and also the pressures exerted by the water vapor at these maximum capacities, the values being taken directly from the steam tables of Marks & Davis, Table I

Temperature °Fa	Max Capacity Lbs/Cu Ft Space	Vapor Pressure Lbs/Sq In
32	000304	.0886
40	000410	.1217
50	000587	.1780
60	000828	2562
65	000977	3054
70	001148	3626
75	001346	4288
80	001570	505
85	001832	594
90	002131	696
95	002469	.813

To obtain grains/cu ft multiply lbs/cu ft by 7,000

The extent to which what Dr Gulick calls the "thirst" of air for more water vapor is unsatisfied is the difference between the maximum capacity and the quantity actually present The rapidity with which moisture is evaporated from a moist surface, such as the skin, probably depends, first, on the "thirst" of the air, second, upon the velocity with which the air moves across the moist surface; and third, upon the physical condition of the moist surface, particularly with respect to temperature. Relative humidity is ratio of the quantity of water vapor actually present to the maximum quantity that could be present at a given temperature. Relative humidity will not of itself determine air "thirst," as this "thirst" will be different for the same relative humidity at different temperatures.

Dr Gulick asks, "Does any one know why delicate children and tuberculous persons get well out of doors but fail to do so indoors" I am not a physician but do believe the air "thirst" is certainly, as a rule, far greater indoors than out of doors, and that this "thirst" continually absorbs moisture from the skin, tending to keep it cold and dry and chilling it in local spots

WILLIAM J CROWELL, JR, CH E

TO THE EDITOR OF SCIENCE The capacity of gases for carrying vapors of volatile liquids and the capacity of various volatile liquids to take the vapor form is a subject to which the writer recently has had occasion to devote considerable thought in connection with certain technical processes Possibly some of the confusion which it seems exists in Dr. Gulick's mind may be dispelled by the following statements which I think can be readily verified.

I will attempt to answer the questions propounded by Dr Gulick on page 327 of the March 3, 1910, number of SCIENCE.

1 Water vapor, I believe, is the correct term to be used in a discussion of the hygienic effect of atmospheric humidity since the word steam sometimes conveys the meaning of the cloud of minute water particles resulting from condensation of water vapor in the presence of another gas (air).

2 Water vapor then (the amount of which, compared with the total capable of being carried, in the air at any temperature represents its humidity) does "act strictly in accordance with the ordinary laws governing the movement of gases."

3. Humidity in the air is a term used to express the amount of water vapor in the air usually expressed in terms of the percentage of the total amount capable of being carried at that temperature.

4. Water vapor (as long as it remains in

the vapor form) is a gas and obeys all the laws of gases

5 Air has only the same capacity for carrying any vapor (water vapor) that any other gas has

6 The amount of humidity (i e, the basis for calculating percentage humidity) that air, or any other gas, can carry is not a function of the nature of the gas at all

7 The amount of any vapor that any gas can carry depends solely upon the nature of the substance vaporized and the temperature

8 The actual percentage by volume of vapor which any gas (air) can carry, i. e, the saturation point, is determined by the following formula:

$$\text{Per cent} = \text{Pt}/\text{Atm}$$

Where Pt = vapor tension of the liquid at temperature t, and Atm = pressure of the atmosphere The vapor pressure (the force which a substance exerts to take the vapor form) of water and most common liquids is given in physical tables for all ordinary temperatures

For example, at 20° C (68° F) water has a vapor tension of 17 363 millimeters of Hg Air saturated with water vapor at 20° C, therefore, contains 2 28 per cent If it only contains 1 14 per cent, its humidity is only 50 per cent At 0° C (32° F) the vapor tension of water is 4 569 mm and air saturated at 0° C, therefore, carries only 6 per cent. water vapor, or considerably less than if only 50 per cent. saturated at 20° C

9 Strictly, air is not altered by increase in temperature so that it can carry more water vapor, but the liquid producing the vapor is changed so that it has a greater vapor tension and a proportionately greater percentage of vapor will enter the air

10. The rate of evaporation then from any given moist surface depends upon the actual amount of water the air is capable of taking up (not on the *percentage* of unsaturation) and upon the relative rapidity of movement of the air.

For example, from a square centimeter of skin surface with saturated air no evaporation can take place at any temperature At 20° C, however, and 50 per cent humidity, let us say that 1 14 milligrams are vaporized per minute, then at 0° C and 50 per cent humidity only 3 milligram would be vaporized in the same time Even absolutely dry air at 0° C evaporates less moisture than at 20° C and 70 per cent saturated This is on the assumption that the skin is equally moist at both temperatures and that there is equal movement or no movement of air in both cases

The amount of moisture that may be in the air, whether greater or less, can have no physiological effect, for that already there can be considered a dry gas There need only be considered whether or not conditions are such that much or little or none can be evaporated

11 Perhaps the normal human organism requires the removal of the heat produced by mental or physical activity at a certain fairly definite rate In such case both heat carried away by radiation and by evaporation must be considered, one in a measure supplementing the other Low temperatures increase radiation and decrease heat loss by evaporation and *vice versa*

For example, one extreme condition would be when the air is saturated with water vapor and at or above the body temperature The body then has lost all temperature control At any lower temperature there still remains radiation though the air be saturated.

The other extreme condition would be for extremely low temperatures where, though there is little cooling from evaporation and little moisture produced for evaporation, radiation is excessive and the only remedy is the prevention of radiation by additional clothing

Fortunately at low temperatures when radiation is high, there is little loss from the latent heat of evaporation because air at low temperatures, even if perfectly dry, can carry away little water vapor. In addition to this balance of effect from outside influences, there is the most important physiological influence of perspiration increasing or decreasing the moisture to be evaporated.

Is it not possible, therefore, that the best

physiological condition is that where heat loss by radiation just balances that produced and there is little or no use for perspiration and its evaporation In other words, is not the physiological process of perspiration exhausting and only necessary because the atmosphere is too hot to permit of removal of heat by radiation without the aid of positive physiological effort?

In Atwater's and Benedict's experiments the data given should show the amount of water eliminated to the air from the breath and through the skin This represents a definite number of calories absorbed and should show under the conditions the relation of the amount of heat removed by evaporation to that removed by radiation

These suggestions are made, as you can see, by a novice in hygiene but they may possibly throw a little side light on the problem

LOUIS CLEVELAND JONES

UNIVERSITY FELLOWSHIPS

TO THE EDITOR OF SCIENCE In SCIENCE of February 10, just at hand out here, there appears a letter by Dr. S N Patten upon which I would like the privilege of commenting

The letter divides itself into two main contentions

First, by means of a table of present occupations, an attempt is made to show the prosperity of a group of "fellows," thereby demonstrating the value of fellowships To prove the point the investigation would have to be conducted along lines similar to those recently followed in another connection by Professors Furman, of Stevens Institute, and Cooley, of Michigan[1] As it is, the surface indications presented by this table lead—through the legitimate inferences which may be drawn—to a conclusion diametrically opposite to the one there stated.

Of the 183 fellows listed as living and of known occupation, 27 belong to a group comprised of literary workers, social workers, ministers and students To assume any of these wallowing in a wealth of financial returns offers difficulty to the imagination.

[1] *Proc Soc. for the Prom of Eng Ed.*

The second group, 138, consists of 31 teachers in normal and secondary schools and 107 instructors and professors Lacking specific knowledge as to these individual cases it is fair to reason that these men are no better off than the average of similar ages in their profession From a knowledge of the prevailing conditions it would be proper to assume that $1,200 would not be far from the average salary of this group Under present-day conditions this looks more like "starvation" to me than, perhaps, it does to one who pictures to himself living on an equal salary at the same age, under the conditions of thirty years ago.

This disposes of all save 18 experts and business men Lacking specific evidence, it is fair to presume that this 10 per cent is financially more prosperous than the other 90 per cent

I hope that Professor Patten will complete his table, adding, for instance, the individual ages and salaries This would give a chance for comparison with an equivalent group of non-fellows, at all events, it would transfer the matter from the realm of speculation to that of hard fact.

But it is the second of Dr Patten's contentions which interests me more. He lays down the dictum that it is "rapidity of promotion and not lack of it that ruins promising investigators" To sustain this he gives a couple of inconclusive instances. In neither case are the returns, upon which to base final judgment, yet in

To test his statement I jotted down a list of American scholars whose names occurred to me offhand, for one reason or another Then I looked up their date of birth and of call to full professorship The table follows, and the only name on my list omitted below is that of William James, whose call was deferred to his forty-third year because he started out in the field of anatomy and physiology and when he shifted to philosophy had his apprenticeship term as assistant professor to serve all over again.

Does this list bear out the conclusion that an early call or rapidity of promotion is the

ruin of promising scholars? I, for one, should like to see a much longer list like the foregoing compiled by, let us say, the editor of "American Men of Science." It would be interesting to see the result.

Name	Year of Birth	Year of Call	Age at Call
Gray, Asa	1810	1842	32
LeConte, Joseph	1823	1852	29
Gibbs, J. W.	1839	1871	32
Rowland, H. A.	1848	1876	28
Michelson, A. A.	1852	1883	31
Remsen, I.	1846	1872	26
Brooks, W. K.	1848	1876	28
Gildersleeve, B. L.	1831	1856	25
Hale, W. G.	1849	1880	31
Welch, W. H.	1850	1879	29
Osler, W.	1849	1874	25
Wilson, H. V.	1856	1885	29
Thurston, R. H.	1839	1871	32
Walker, F. A.	1840	1873	33
Fisher, I.	1867	1898	31
Sumner, W. G.	1840	1872	32
Giddings, F. H.	1855	1888	33
Clark, J. B.	1847	1877	30
Carver, T. N.	1865	1894	29
Seligman, E. R. A.	1861	1891	30
Ely, R.	1854	1881	27
Commons, J. R.	1862	1892	30
Patten, S. N.	1852	1888	36

If "young men should be left alone until they are fully developed before transplanting them" they form a curious biological exception. It is a novel contention that prolonged subordination best prepares for initiative and resourcefulness—for intellectual independence and leadership.

If "scholars are not born, they are made by their environment," some change in environment during their period of greatest growth might possibly prove to be stimulating and broadening—particularly if the change were such as, by offering easier financial conditions, freed their time from, let us say, assisting overworked wives in household duties.

The picture of President Jordan conducting a publicity bureau and "dragging into the limelight young men that it would have been better to leave alone" is enjoyable—their being in the statement just enough of that element of contrast which is the essence of humor.

It is true that President Jordan, at the opening of Stanford, called a group of professors whose ages ranged from 31 to 42 years, all but two of them, however, holding full professorships elsewhere at the time—but I, for one, am unaware of his having ever dragged any one of these, or his subsequent appointees, into the limelight. As for these subsequent appointees, their ages have been about 40, I should estimate, as an average. Stanford has offered no marked exception to the general trend of increasing age at promotion to full professorship.

In conclusion, I would like to say that it is significant to note the discussion called forth by the comparatively trivial question of fellowships, contrasted with the silence on the really vital subject presented in John Jay Chapman's letter to SCIENCE last summer. I wish you would reprint that communication now that the season of academic vacation is past.

GUIDO H. MARX

STANFORD UNIVERSITY, CAL.,
February 17, 1911

UNIVERSITY FELLOWSHIPS

TO THE EDITOR OF SCIENCE: Reading Dr. Patten's criticism of Dr. Jordan's address I must protest against the whole tone of his argument, which seems to be that the inducements offered by the teaching profession are so promising and the chances of rapid promotion so great that they tend to prevent the production of scholars. I wish to give the view of a young man just facing the career of a teacher.

Dr. Patten's statement that "scholars are not born" is open to serious criticism. That they are "made by their environment" is partly true. I would extend this statement to read: "and also unmade by their environment," and this environment is a teaching position at $1,000 to $1,500 a year. He does not state how many of the 188 University of Pennsylvania fellows teaching in universities and secondary schools are struggling along on $1,500 or less trying to pay off debts. He does not state how many of them are unmarried because they can not afford it. I heard a

professor say that a young teacher should not get married, because the profession does not offer a living for two Is this the price a man must pay for learning? Is it worth while? Does it lead to scholarship?

The assistant professor with a family can not, on $1,500 a year, get the necessary literature and books, he can not attend meetings at a distance, or travel and gather knowledge and inspiration from others of his kind Does this lead to scholarship? Is it an inspiration for a university fellow to teach at $1,000 a year in a secondary school? Does this indicate that the market is not overstocked?

I raise a question as to whether "it is the professor that needs endowment" if we are to produce scholars. One reason there are not more scholars in America is because the entering inducements are not sufficient Men prepare for the teaching profession and then turn aside for more remunerative work In the zoological laboratory at Columbia University last year there were five students about ready to come up for the Ph.D degree Of these, three signified their intention of abandoning their plans of following the teaching profession. It is the young men who abandon the call of scholarship They are the ones who need encouragement. It is the getting of more men into the profession that will produce scholars as well as helping those already in it. From the many will come the few real scholars that the nation can produce and these will be the result of heredity as well as of training.

It has been claimed that the greatest intellects in America are among the business men. This may be partly true. If the inducements of the teaching profession had been greater some of these men would, doubtless, be leading scholars to-day.

Dr. Patten's hopes of a promising man are that he will settle down on $1,500 a year, forgetting that he has a family to provide for, that he needs literature, travel and association with others. I can not forget seeing a university instructor spending his vacation wheeling a wheelbarrow. This is not going to produce scholars. It produces assistant professors without enthusiasm or inspiration. The teaching profession is bad enough Why make it worse?

The idea that "no one should have the title of professor until it was fully earned" is good But he should be supported while he is attempting to earn it. If this were done more generously than at present more men would make the attempt. Poverty does not offer a smooth road to learning

SABIN, Baltimore, G L STREETER, Michigan; J TANDLER, Vienna, E ZUCKERKANDL, Vienna Edited by FRANZ KEIBEL and FRANKLIN P MALL. In two volumes Volume I 550 pp, with 423 illustrations Philadelphia and London, J. B. Lippincott Company 1910.

The publication of this work is worthy of very special notice, for it may well be said to mark an epoch of accomplishment in the study of human embryology, while on the other hand it furnishes exceptionally numerous suggestions of many problems yet to be solved, with the most promising lines of attack.

In the introduction, Professor Keibel brings out vividly, after an excellent historical review, the conditions which led up to the inauguration of the modern study of human embryology by Wm. His. It is fortunate that the great volume of these studies which have been accumulated under this inspiration should now be so fully reviewed and made available by the cooperation of these students of his. The plan of His for an extended exposition of human embryology is thus finally accomplished under the leadership of Keibel and Mall on two sides of the Atlantic

Examination of the first volume gives quite a different conception of the field of human embryology from that obtained from other older text-books on the subject; for instance, Minot's very successful and constructive text-book of twenty years ago. It was evident then that, though much valuable work had already been done in various lines, it was still of a scattered character and unorganized. The effect, as a whole, was inconclusive. There were very few topics which had been studied with thoroughness or on sufficient human material.

In the new book we find that a considerable mass of fresh facts and accurate information have been accumulated, from intensive and systematic studies of a far more complete series of embryos, by more effective methods. Though much remains to be done in every department of investigation, it is now clear that the study of human embryos has become organized. Extensive collections are accessible. There is a systematic effort to obtain more complete records in every chapter of the history. The comparative and experimental method is not less used, but has become more an aid to interpretation, while the results secured from the study of human material itself now overshadow all else.

Another striking feature of the new book is the fact that it is the product of a cooperation between so many active American anatomists with well-known Germans, and that it is published, at the same time, in two languages. This is not only a recognition of the extent of His's influence, and of the general wide growth of a cooperative spirit in scientific anatomical research, which has become very marked in this science; it is also a substantial appreciation from abroad of the effective work which has been done in embryology among our anatomists in recent years. Almost every chapter of the book enforces this fact, and the use of illustrations and references to contributions from Americans published in the *American Journal of Anatomy* is frequent. Nine of the fifteen editors are Americans and, of these, five are pupils of Dr. Mall, whose initiative and stimulating example have encouraged much of the activity in embryological investigations of this character in this country.

Keibel writes the more general chapters in the first part (90 pages), including the historical introduction, the account of the germ-cells, fertilization, segmentation, young human ova, germ-layers and gastrulation, and a general summary of the development of the embryo. The rather restricted space given to these topics, which are treated so extensively in Hertwig's "Handbook of Comparative Embryology," is an illustration of the limitation of the scope of the new work to the results of the study of human material. Much of the greatest interest connected with these topics is here necessarily omitted, but there is a decided advantage in exhibiting the actual status of our knowledge. All through these chapters Keibel's fine critical judgment is evident. One receives the true impression that the writer has thorough personal familiarity with the facts. Nowhere is a nice judicial decision in such demand as in discussions about young human ova, hence we are especially glad to find this chapter by Keibel, whose treatment is masterful and illuminating. The tables are new and the details of comparison of young stages are satisfactory. The reader has an opportunity to secure a necessary amount of detail often lacking, confused or pointless in other accounts. The obstetrician will find much of interest here. Keibel's discussion of germ-layers is especially well put. The summary and résumé of the general history of the embryo based on the His and Keibel-Elze Normentafeln of human embryos is excellent, the little critical accounts of each important embryo being well worth while.

Grosser's long chapter (90 pages) on menstruation, implantation, placentation, membranes, etc., is based on extensive personal investigations. This account is almost a monographic treatment of these subjects. The obstetrician will find a mine of discoveries in this chapter and the two following ones. The trophoblast, chorion, villi, decidua,

placenta, menstruation, ovulation, age of embryos and other related topics are given proper attention, and put in the most modern light An excellent basis is laid by precise description for further work in the histological or pathological study of membranes and uterine conditions, and a better idea is now possible of the physiological environment of early embryos, especially from the new young human embryos described in detail

In his chapters (60 pages), Mall advocates a new and improved method of measuring embryos, which may also be applied to the adult His analysis of our knowledge of the age of embryos, growth rate, etc, is original, and results in new curves and tables of development He thus furnishes us a standard, the result of a wide experience with all known data His chapter on pathological embryos is novel and an advance in view point It represents the essentials of his very extensive publications on this subject The types of abnormalities, percentage of abortions, and the association of the pathology of the membranes with these are discussed This leads up to an analysis of the bearing which experimental studies, mechanical and chemical, leading to the production of definite monstrosities in other forms, probably have on the origin of abnormalities in human embryos Medical students and pathologists will turn to these chapters freely, and general embryologists will find here interesting significance in their work.

The second half of the first volume is devoted to the first chapters of the development of special systems of organs, which will be continued in the second volume. An examination makes it plain that these chapters were not written for beginners, though the treatment is direct and clear enough for any one Even this first volume is sufficient to show that there is now ample material for satisfactory courses in mammalian embryology of advanced character, specially adapted to medical students.

It is evident that the time has come for our anatomical departments to insist that students beginning anatomy should have already obtained, during their two years of pre-medical college work now generally required, sufficiently thorough courses in elementary vertebrate embryology, to permit of properly introducing them to the later stages, in man and mammals, which have so much significance for their work in human anatomy.

The fifty pages by Pinkus, devoted to the integument, proves to be a consideration of many interesting aspects of the growth of the skin structures often not insisted upon For in the treatment of pigmentation, glycogen, fat, glands, hair and hair tracts, and of the friction ridges and metamerism, we have emphasized the value of more general studies like those of Galton, Wilder, Sherrington, Bolk and Harrison The special circulation, lymph supply, and nerve supply of the skin are largely left for the writers who shall describe these systems

Bardeen's section (150 pages) on the skeleton and connective tissues may be characterized as encyclopædic in the inclusion of so great a mass of data It is a storehouse of information, the variety of which has made the task of collecting and arranging very difficult The author has exhibited much energy and skill in handling the material, to which he has contributed considerable of value Mall's views are accepted as the most reasonable for the origin of the reticulum and fibrillæ of this tissue Some of the most welcome sections on the skeleton are those on joints, and on variation and abnormalities in development The origin and changes of form of vertebræ are illustrated by Bardeen's models, a set of which should be found in every anatomical laboratory The treatment of the development of special regions of the skeleton, of ossification centers, of the length and curvature of the spine, is accompanied by valuable figures and diagrams The skeleton of the limbs is taken up with similar fulness and contains further contributions from the author, many figures new to text-books, and useful tables The skull is studied in forty pages with a proper reference to comparative embryology where also much has been done, and such important complicated regions as the

orbit, temporal and nasal regions, and the visceral arch derivatives are considered separately. The author publishes, for the first time, two new views of the skull of a twenty-millimeter embryo which combine numerous interesting relations. It is a pity that the details of these figures are not better shown in the half-tones. Anatomical illustrations are being steadily improved, and this is shown in many figures in this edition; but far more care is yet required in both the printing and selection of suitable paper, before the standard of German editions can be approached. The chapter closes with an extended account of the ossification of the individual bones of the skull.

The development of the muscular system is described by W. H. Lewis in about seventy pages. We find this an excellent account, well planned and comprehensive, while at the same time concise and logical. The influence of a participation on the part of the writer in embryological studies of an experimental nature is quite evident and gives a modern point of view.

The chapter is well illustrated, many of the figures being original, and some published here first. It is possible to obtain from them and the text a good idea of the origin and development of the various muscle groups. The author's contributions to the development of the muscles of trunk and limbs, and more recently of the head, tongue and larynx, are outlined here with figures from his new models. Futamura's striking series of pictures representing the stages of spreading of the facial musculature forms an interesting feature.

Only twenty-four pages are allotted to the last section, including the septum transversum diaphragm, and the cœlom, but the subject is brought up to-date by Mall with the aid of new investigations in addition to his previous extensive studies and the conditions found in a number of recently described young human ova. Broman's work is also incorporated to advantage.

One praiseworthy feature is the extensive bibliography at the end of each chapter.

Though the printing of the illustrations and the general make-up of the German edition is decidedly superior to the English, the American publishers have, on the whole, succeeded in making the volume a creditable one. The second volume, now in press, will be anticipated with much interest.

THE ORIGIN OF NINE WING MUTATIONS IN DROSOPHILA[1]

IN the following preliminary report I wish to put on record some of the principal wing mutations that have appeared in cultures of the fruit fly, *Drosophila ampelophila*. In another communication I shall describe five mutations in eye color that have been found in the same cultures, and their modes of inheritance. The theoretical questions involved must be deferred until the complete data can be published. These mutations have appeared in such rapid succession that my time has been almost entirely consumed in producing pure strains of the new forms, which can be utilized later for a thorough study of the inheritance of the new types. I wish here merely to call attention to the fact that while most of the new types breed true from the start, others do not; and also to the fact that while certain of the mutations are sex-limited other mutations involving the same organs do not show this form of inheritance. It may appear that we have here an opportunity to learn something further of these different modes of inheritance appearing in the same animal. One fact especially will impress itself on any one who follows the history of these new types, viz., the "segregation" of the characters, and in most cases the absence of intergrades.

Beaded Wings.—In May, 1910, a number of flies, pupæ, larvæ and eggs of *Drosophila* were subjected to radium rays. One fly was pro-

[1] The main facts in this paper were given before the American Society of Zoologists, December 29, 1910.

duced, the marginal vein of whose wings was beaded Bred to his sisters, the beaded condition appeared in one fly in sixty of the next generation The beaded flies were inbred and produced in the third generation, one beaded winged fly to thirty-five normal The beaded flies produced in the next generation one beaded to twelve normal wings The same process continued through many generations has finally produced stock that gives in certain cultures nearly 100 per cent beaded wings

Not only has selection slowly increased the percentage of abnormal wings, but much more extreme forms of the same variation have appeared, and an attempt is now being made to fix some of these extreme variations

When a beaded male of the stock in its present condition was bred back to the wild females the beaded condition appeared in one fly in twelve of the first generation In the second generation from non-beaded flies the proportion was one to twenty

In the further course of the experiment eight other modifications have appeared that are undoubtedly mutations, one confined largely to females, some of the others showing strictly alternate inheritance, combined with "sex-limited transmission" These modifications may be described under the following headings
